A.A. Zainal Abidin
Universiti Teknikal Malaysia Melaka, Durian Tunggal, Melaka, Malaysia

PREFACE

The *Encyclopedia of Renewable and Sustainable Materials* is a novel initiative, launched to cater for researchers, industrial practitioners and environmental conservationists to bring to the fore the issues of renewability, regeneration, recyclability and sustainability of natural material resources for the greater good of the environment, society and renewable resources. With these objectives the project was constituted of 11 sections, led by one Section Editor each. There are about 4,000 printed pages, accommodated in five volumes ranging from 600 to 1000 pages each.

This encyclopedia is the primary reference source for researchers at different levels and stages in their career in academia and industry and those with an interest in environmental protection and sustainability, including re-use and recycling of natural and synthetic materials and regeneration of natural materials. The work encompasses the knowledge and understanding of many experts into a single, comprehensive work of about 370 articles comprising a combination of review articles, case studies and research findings resulting from research and development activities in both industrial and academic domains. The encyclopedia, focuses on how some of these topics bring advantages for a broad range of technologies and environmental protectionists. These include harnessing existing materials both natural and synthetic, their re-usability and regeneration possibilities for the greater good of society and the environment. The aspects of feasibility, conservational objectives and practicability of implementation have been addressed through a number of relevant articles.

As Editors in Chief of this five-volume comprehensive publication, a truly collaborative work, we are greatly indebted to the 11 Section Editors who are internationally renowned experts in their fields, for guiding and selecting the topics for their respective sections which constitute the five volumes, commissioning authors and reviewing the contents so meticulously. Their true dedication to the scientific community and society is reflected in the time and energy they have given to this project. My sincerest thanks are due to all the authors – researchers, environmental protectionists and practitioners who have contributed extensive coverage of literature review as well as recent works of research to this substantial five volume encyclopedia. The excellent insight and specialist knowledge in their respective fields is reflected in the high quality content of this unique work.

Both of us and all the section editors are greatly appreciative of all the hard work undertaken by all concerned to turn this concept of the *Encyclopedia of Renewable and Sustainable Materials* into a publishable work. Our special thanks go to Ruth Rhodes and Michael Nicholls, the Project Manager, along with Kshitija Iyer and the rest of the team at Elsevier who served successively to keep the project on track through friendly nudges in order to ensure timely completion. We are also hugely grateful to other colleagues at Elsevier production unit for the coordination of the proofs.

The extensive research treatment of core ethos of renewability, recyclability and regeneration, supplemented by applied case studies has drawn together many areas of research and we sincerely hope that this work will prove to be of great help to both the young and experienced members of the international research community, academics and industrial practitioners associated with sensible utilization of natural and synthetic materials for many years to come.

Saleem Hashmi and Imtiaz Ahmed Choudhury
Editors in Chief – *Encyclopedia of Renewable and Sustainable Materials*

CONTENTS OF ALL VOLUMES

Editorial Board	v
List of Contributors to Volume 1	vii
Preface	xiii

VOLUME 1

Eco Friendly Materials and Technologies

Advent of an Agro Friendly Approach in Bangladesh <i>Mohammad Abu Sadeque, Tamanna Rahman, and Mohammad Tosnimul Hassan</i>	1
Analysis of the Indian Traditional <i>Loha Shodhana</i> Process for Biocompatibility <i>BP Hari Chandra and SV Prakash</i>	26
Analyzing Biodiesel Production From Cooking Oil <i>Dalibor Petković</i>	33
Application of Nano Porous Materials for Energy Conservation and Storage <i>Ranvijay Kumar and Rupinder Singh</i>	42
Application of Nano Porous Materials for Energy Conversion Process <i>Rupinder Singh and Ranvijay Kumar</i>	51
Appraisal of E-Drought System Based on Object Oriented Approach <i>Dalibor Petković</i>	56
Bamboo Fiber as Fillers for Polypropylene-Nanoclay via Injection Molding <i>Mohd H Othman</i>	60
Challenges and Developments of Rubber Materials as Vibration Isolator <i>Mohd A bin Salim, Siti H binti Sheikh Md. Fadzullah, Ghazali bin Omar, Mohd Z bin Akop, Nurfaizey bin Abdul Hamid, and Noreffendy bin Tamaldin</i>	64
The Circular Economy: Additive Manufacturing and Impacts for Materials Processing <i>Lorna Fitzsimons, Greg McNamara, Muhannad Obeidi, and Dermot Brabazon</i>	81
A Comparative Life Cycle Assessment for Utilising Laminated Veneer Bamboo as a Primary Structural Material in High-Rise Residential Buildings <i>Philip Kavanagh, Jim Roche, Noel Brady, and John Lauder</i>	93
A Comprehensive Study for 3D Printing of Rapid Tooling From Reinforced Waste Thermoplastics <i>Piyush Bedi, Rupinder Singh, and Inderpreet S Ahuja</i>	114
CO ₂ Laser Cutting of Glass Fiber-Reinforced Plastics <i>Hayat A Eltawahni, Abdul G Olabi, Osama M Basmage, and Khaled Y Benyounis</i>	145
CO ₂ Utilization Drivers, Opportunities and Conversion Challenges <i>Naeem Abas, Nasrullah Khan, Aun Haider, Shahid Iqbal, and Muhammad Shahbaz</i>	160
Design and Performance Analysis of Small-Scale Parabolic Trough Solar Collectors Using Sustainable Materials <i>Ahmed A Shawky and Adel KH Khalil</i>	172

Development of Epoxy Based Composites Using Bamboo and Waste Metal Chips <i>Arun C Borsaiikia, Anup Kumar, Amit Raj, and Uday S Dixit</i>	181
Development of HAp Reinforced Biodegradable Porous Structure Through Polymer Deposition Technology for Tissue Engineering Applications <i>Nishant Ranjan, Rupinder Singh, and Inderpreet S Ahuja</i>	196
District Heating Systems From Environmental Waste <i>Dalibor Petković</i>	216
E-Agriculture System by Object-Oriented Approach <i>Dalibor Petković</i>	221
Eco Friendly Aspects in Hybridization of Friction Stir Welding Technology for Dissimilar Metallic Materials <i>Swarup Bag and Esther T Akinlabi</i>	225
Eco Friendly Flocculants: Synthesis, Characterization and Applications <i>GP Karmakar</i>	237
Electrochemical Energy Storage Using Batteries, Superconductors and Hybrid Technologies <i>Kamaljit S Boparai and Rupinder Singh</i>	248
Energy Efficiency Analysis in Building Walls in Tropical Climate Using Thermal Insulation System <i>Md M Rahman, TMI Mahlia, and Md N Uddin</i>	255
Energy Efficient Composite Materials <i>Anita Mohan</i>	262
Environmental Analysis Waste Management Model <i>Dalibor Petković</i>	273
The Environmental Challenges Associated With the Anaerobic Digestion Process when Applied Extensively <i>Alla M Alrefai, Raid Alrefai, Joseph Stokes, and Khaled Y Benyounis</i>	279
Experimental Investigation of Microtest Specimens of Renewable Material-Based Composite Materials by Injection Molding <i>H Chin How and M Azuddin</i>	287
Experimental Investigations for Development of Aluminum MMC With Hybrid Reinforcement and Vacuum Molding <i>Swarndeep Singh, Rupinder Singh, and Simranpreet S Gill</i>	301
Experimental Investigations for Development of Conductive Ceramic Composites with Microwave Sintering and Their Electric Discharge Machining <i>Mandeep Singh, Rupinder Singh, and Simranpreet S Gill</i>	312
Food Waste for Sustainable Packaging Materials <i>Valentina Siracusa</i>	322
Global Economy Increasing by Enterprise Resource Planning <i>Nebojša Denić, Dalibor Petković, and Boban Spasić</i>	331
High Dynamic Range Imaging and its Use in Daylight and Lighting Design <i>Anne Gorman and Antonello Durante</i>	338
Induction Heating in Sustainable Manufacturing and Material Processing Technologies – A State of the Art Literature Review <i>Ankan Mishra, Swarup Bag, and Sukhomay Pal</i>	343
Investigation of the Fuel Value of Selected Wood Samples Using Artificial Neural Networks <i>MG Yazdani, MA Salam, QM Rahman, and O Malik</i>	358

Investigations for Barium Titanate and Graphene Reinforced PVDF Matrix for 4D Applications <i>Ravinder Sharma, Rupinder Singh, and Ajay Batish</i>	366
Investigations for Metal Matrix Composites Prepared by Using Waste Polymer-Based Sacrificial Rapid Pattern in Investment Casting <i>Narinder Singh, Rupinder Singh, and Inderpreet S Ahuja</i>	376
Investigations for Rapid Tooling Prepared With Waste Polymer-Based Hybrid Filament <i>Piyush Bedi, Rupinder Singh, and Inderpreet S Ahuja</i>	385
Large Biomass Burners for Fuel Switch in Existing Fossil Fuel Based Plants <i>Dalibor Petković</i>	403
Machine for Producing Tablets From Coal Powder <i>Dalibor Petković</i>	407
Manufacturing, Applications and Mechanical Properties of Lightweight Wood-Based Sandwich Panels <i>Khameel B Mustapha</i>	411
Materials, Design and Development of Latent Heat Storage Systems for Medium and Large-Scale Applications: Issues and Challenges <i>Palanisamy Muthukumar and Hakeem Niyas</i>	417
Metallic Materials From E-Waste <i>Manojit Ghosh, Debashish Sur, Shibani Basu, and Partha S Banerjee</i>	438
Modeling Estimation and Performance Evaluation for Vibration Isolators <i>MA Salim, MR Mansor, SH Sheikh Md Fadzullah, and G Omar</i>	456
Modeling of Information System for Air Waste Management <i>Dalibor Petković</i>	470
Modeling of Information System for Liquid Waste Management <i>Dalibor Petković</i>	479
Modeling of Information System for Nuclear Waste Management <i>Dalibor Petković</i>	490
Modeling of Information System for Solid Waste Management <i>Dalibor Petković</i>	497
Multi-Stage Stamping of Lightweight Steel Wheel Disks by Controlling its Wall Thickness Distribution <i>Chin Joo Tan</i>	510
Nanomaterials <i>Shahida Begum, Abu NM Karim, Mohamed NM Ansari, and Mohamad SJ Hashmi</i>	515
Nano-Porous Materials for Energy Conversion Using Green Technologies <i>Salah A Elsheikhi and Khaled A Eldressi</i>	540
Nano-Porous Materials for Use in Solar Cells and Fuel Cells <i>Md Abdullah Al Mamun, Manifa Noor, Muhammad Hasanuzzaman, and Mohamad SJ Hashmi</i>	549
Natural Lignite Resources in Kosovo and Metohija and Their Influence on the Environment <i>Boban Spasić, Boris Siljković, Nebojša Denić, Dalibor Petković, and Vuk Vujović</i>	561
New Educational Models to Train Engineers and Executives On Eco Friendly Technologies, Products and Sustainability Policies <i>Emmanuel Koukios, Lazaros Karaoglou, Sofia Papadaki, Dimitrios Koullas, and Nikolaos Kourakos</i>	567
Nuclear Electricity – Renewability, Losses and Recycling <i>Manojit Ghosh, Shashank Sharma, and Partha S Banerjee</i>	575

Open Volumetric Air Receiver: Current Status, Challenges and Innovative Solutions <i>Gurveer Singh, Salvador Luque, José González-Aguilar, Manuel Romero, and Laltu Chandra</i>	586
Opportunities for Digital Marketing in the Viticulture of Kosovo and Metohija <i>Nebojša Denić, Dalibor Petković, Boris Siljković, and Ratko Ivković</i>	600
Optimization of Electrical Energy Usage in Two Secondary Schools Using Different Types of Glass Materials <i>Md Gholam Yazdani, Md Abdus Salam, Quazi Mehbubar Rahman, Raadhiya Sofri, and Azriea Kamal</i>	616
An Overview of the Global Ship Recycling Industry <i>Kanu P Jain and Jeroen Pruyn</i>	626
Plastic Products in Hospitals and Healthcare Systems <i>Osama M Basmage and Mohamad SJ Hashmi</i>	648
Post-Processing of HVOF Sprayed WC-Co Coating to Enhance its Performance <i>Gourhari Ghosh, Ajay Sidpara, and Partha P Bandyopadhyay</i>	658
Potential of Co-Fired Fly Ashes as a Construction Material – A Review <i>Shashi Ram, Meghna S Tare, Pranesh B Aswath, and Rahul V Ralegaonkar</i>	674
The Production of Biogas, Biodiesel as High-Value Bio-Based Product and Multiple Bio-Products Through an Integration Approach of the Anaerobic Digestion and Fermentation Processes <i>Raid Alrefai, Alla M Alrefai, Joseph Stokes, and Khaled Y Benyounis</i>	686
Prospect of Recycling of Plastic Product to Minimize Environmental Pollution <i>Ranvijay Kumar and Rupinder Singh</i>	695
Recent Advancement and Challenges of Additive Manufacturing Geospatial Images Solution Integration <i>AA Zainal Abidin, MA Salim, A Md Saad, G Omar, and MZ Akop</i>	704
Recycled Clothes With Polypropylene-Nanoclay for Industrial Product via Injection Molding <i>Mohd H Othman</i>	713
Renewability and Sustainability: Current Status and Future Prospects <i>Sayyad Z Qamar and Mahmoud Al-Kindi</i>	717
100% Renewable Energy by Renewable Materials <i>Dalibor Petković</i>	731
Reuse of Waste Corrugated With Coir Fibers as a Packaging Material <i>Mohd H Othman</i>	734
A Review on Utilization of Electronic Waste Plastics for Use Within Asphaltic Concrete Materials: Development, Opportunities and Challenges for Successful Implementation <i>Mohd Rosli Mohd Hasan, Baron W Colbert, Zhanping You, Xu Yang, Meor Othman Hamzah, Qingli Dai, Hainian Wang, and Aboelkasim Diab</i>	737
The Role of Engineering in Mitigating Global Climate Change Effects: Review of the Aspects of Carbon Emissions from Fossil Fuel-Based Power Plants and Manufacturing Industries <i>Mollah S Islam, Shahnur Begum, Mussen L Malcolm, Mohamad SJ Hashmi, and Mohammad S Islam</i>	750
Rubber Scrap as Reinforced Material in the Production of Environmentally Friendly Brake Lining <i>SA Lawal, IC Ugwuoke, J Abutu, RA Lafia-Araga, IM Dagwa, and I Kariim</i>	763
Scaling Up and Intensifying Stakeholders Engagement for Evidence-Based Policymaking: Lessons Learned <i>Charikleia Karakosta and Noriko Fujiwara</i>	773
Simulation and Modeling of Vehicle Emissions – A Review <i>Hussam Achour, Khaled Y Benyounis, Joseph Stokes, Abed Alaswad, Ahmad Baroutaji, Mustafa Sajjia, and Abdul G Olabi</i>	783

Small to Medium Burners for Agricultural Pellets <i>Dalibor Petković</i>	789
Small to Medium Scale Gasification Plant <i>Dalibor Petković</i>	793
Sustainable and Environment Friendly Power Sources for Long Duration Environment Monitoring <i>Jekan Thangavelautham</i>	797
Sustainable Biofuels for Automotive Applications <i>Abhishek Yadav, Shailendra K Shukla, Jeevan V Tirkey, and Saurabh Pathak</i>	809
Sustainable Cutting Fluids: Thermal, Rheological, Biodegradation, Anti-Corrosion, Storage Stability Studies and its Machining Performance <i>Kishor K Gajrani and Mamilla R Sankar</i>	839
Sustainable Machining With Self-Lubricating Coated Mechanical Micro-Textured Cutting Tools <i>Kishor K Gajrani and Mamilla R Sankar</i>	853
Sustainable Materials for Energy Conversion <i>Iman El-Mahallawi, Hussein Badr, Remon Ashraf, and Saeed SI AlMishal</i>	867
Sustainable Materials for Tribological Applications <i>Anita Mohan, Gaurav Gautam, Narendra Kumar, and Sunil Mohan</i>	880
System Optimization for Control of Solid Waste <i>Dalibor Petković</i>	898
Technology for Producing Briquettes From Wet Biomass <i>Dalibor Petković</i>	901
Treatment and Recycling of Domestic and Industrial Wastewater <i>Anne Morrissey</i>	908
Unified Modeling Language for Cooking Oil Management <i>Dalibor Petković</i>	919
Use of Bio-Fibers in Various Practical Applications <i>Anupama Hiremath and Thipperudrappa Sridhar</i>	931
Use of Clayey Salty Soils and its Composite Derivatives for Construction and Ceramics for Household Use in the Thar Desert in India <i>Amrita Kaurwar, Raj K Satankar, Lovelesh Dave, Sandeep Gupta, Jerry Oomen, Mohammad Sharey, Suyog Bodhankar, and Anand K Plappally</i>	936
Use of Novel Nanostructured Photocatalysts for the Environmental Sustainability of Wastewater Treatments <i>Kundan Kumar and Anirban Chowdhury</i>	949
Waste Resources Recycling in Achieving Economic and Environmental Sustainability: Review on Wood Waste Industry <i>MI Shahidul, Mussen L Malcolm, Mohamad SJ Hashmi, and Mohammed H Alhaji</i>	965
Water Resource Management for Renewable and Sustainable Hydro Energy in Turkey <i>Ibrahim Yuksel</i>	975
Nanotechnology in Production and Application of Renewable and Sustainable Materials	
A Numerical Approach to Simulating Oxidation in Thermal Barrier Coatings <i>Farid Saeidi, Ercan Gurses, and Ozgur Aslan</i>	986

VOLUME 2**Natural Renewable Materials**

Bamboo Versus Tubular Steel Scaffolding in Construction: Pros and Cons <i>Paul O Awoyera and Anthony N Ede</i>	1
Biogas Production From Solid Waste Landfill <i>Ivan FS Santos, Regina M Barros, and Geraldo L Tiago Filho</i>	11
Biopolymer-Based Composites for Medical Applications <i>Sathish S Dhilip Kumar, Nicolette N Houreld, and Heidi Abrahamse</i>	20
Biopolymers in the Synthesis of Different Nanostructures <i>Mohammad ET Yazdi, Mohammad S Amiri, and Majid Darroudi</i>	29
Characterization of Wood, Cork and Their Composites for Building Insulation <i>Pragya Gupta and Pradip K Maji</i>	44
Dry/Solid-State Fermentative Ethanol Production <i>Maryam Molaverdi, Safoora Mirmohamadsadeghi, and Keikhosro Karimi</i>	60
Effect of Temperature Dependence of Sorption on Hygrothermal Performance of a Hemp Concrete Building Envelope <i>Anh D Tran Le, Driss Samri, Omar Douzane, Geoffrey Promis, Anh T Nguyen, and Thierry Langlet</i>	68
Energy and Acoustic Performances of Timber in Buildings <i>Marco Caniato, Federica Bettarello, and Andrea Gasparella</i>	78
Environmental Assessment of Green Buildings <i>Pervez H Shaikh, Muhammad S Shaikh, Mahesh Kumar, Faheemullah Shaikh, Muhammad A Uqaili, and Inamullah Bhatti</i>	92
Green Buildings: Risk Factors and Mitigation Measures/Emerging Urban Green Spaces in Dhaka: Planning and Analysis <i>Manifa Rehnuma</i>	98
Green Energy Fuel From Biomass and Sea Water <i>Muhammad B Tahir, Muhammad I Khan, Muhamad Pervaiz, Sidra Arif, Mudassar Maraj, and Muhammad Sagir</i>	114
Green House Effect and Carbon Foot Print <i>Muhammad S Shaikh, Pervez H Shaikh, Khadija Qureshi, and Inamullah Bhatti</i>	120
Hydrogen Evolution Using Advanced Technologies Based on Photocatalysis and Plasma <i>Muhammad B Tahir, Abdullah M Aasir, Muhammad Sagir, Sidra Arif, Ghulam Nabi, Muhammad Rizwan, and Amber Batool</i>	126
Hydrogen Production Through Water Splitting Using Nanomaterials Under Solar Energy <i>Muhammad B Tahir, Tuheed Zahra, Tahir Iqbal, M Rafique, M Shakil, and Muhammad Sagir</i>	132
Jute Pulping: Opportunities and Challenges <i>M Sarwar Jahan and AFM Akhtaruzzaman</i>	136
Life Cycle Assessment of Sisal Fiber <i>Ayyannan Devaraju and Rajasekar Harikumar</i>	144
Nanocellulose Based Aerogels for Varying Engineering Applications <i>Deepu A Gopakumar, Shilpa Thomas, Owolabi F.A.T, Sabu Thomas, Ange Nzihou, Samsul Rizal, and HPS Abdul Khalil</i>	155
Natural Fiber Composites: Review of Recent Automotive Trends <i>S Witayakran, W Smitthipong, R Wangpradid, R Chollakup, and PL Clouston</i>	166

The Nexus Between Biomass – Footprint and Sustainable Development <i>Faik Bilgili and Recep Ulucak</i>	175
Optimization and Kinetic Modeling of Biodiesel Production <i>Chandrasekaran Muthukumaran, Govindasamy Sharmila, Narasimhan Manojkumar, Aruljesu Gnanaprakasam, and VM Sivakumar</i>	193
Performance and Emission Characteristics of Biodiesel–Diesel Blend <i>Mithun Das</i>	202
Performance of Cork and Composites Joints <i>Soumia Mounir, Abdelhamid Khabbazi, Khalid El Harrouni, and Youssef Maaloufa</i>	212
Polyhydroxyalkanoate and Polylactic Acid Composite <i>Md SI Mozumder</i>	223
Polyhydroxyalkanoates (PHA) Production <i>Arumugam Arumugam</i>	236
Properties and End-of-Life of Polymers From Renewable Resources <i>AV Kiruthika</i>	253
Properties of Coconut Fiber <i>S Sengupta and G Basu</i>	263
Recycling of Polylactide <i>José D Badia, Óscar Gil-Castell, Roberto Teruel-Juanes, and Amparo Ribes-Greus</i>	282
Rice Straw as a Raw Material for Pulp and Paper Production <i>Wael A Elhelece</i>	296
Role of Green Polymers in Food Packaging <i>Safoura Ahmadzadeh and Amin M Khaneghah</i>	305
Semiconductor-Based Photocatalytic Nanomaterials for Environmental Applications <i>Muhammad B Tahir, Sidra Arif, Muhammad Sagir, and Amber Batool</i>	320
Structural Integrity Assessment of Bamboo for Construction Purposes <i>Paul O Awoyera and Adeyemi Adesina</i>	326
Sustainability and Recycling of Bamboo for Engineering Applications <i>Paul O Awoyera and Emmanuel I Ugwu</i>	337
Sustainable Biodiesel Production <i>Syed H Shah</i>	347
Yield and Fiber Quality of Cotton <i>Yanjun Zhang and Hezhong Dong</i>	356
Recycling of Renewable Materials	
Bamboo: The Emerging Renewable Material for Sustainable Construction <i>Yingxin Goh, Soon P Yap, and Teong Y Tong</i>	365
Economic Aspects of Fiber Reinforced Polymer Composite Recycling <i>Chiemela V Amaechi, Charles O Agbomerie, Etim Offiong Orok, and Jianqiao Ye</i>	377
Future Eco-Efficient Cements Prepared With Kaolinite-Based Industrial Wastes <i>Moisés F Rojas, Laura Caneda-Martínez, María Isabel Sánchez de Rojas Gómez, and César Medina Martínez</i>	398
Influential Parameters on Formation of PEMs on Recycled Fibers: A Review <i>Hamidreza Rudi</i>	405

Internet of Things Platform to Encourage Recycling in a Smart City <i>Alfonso González-Briones, Pablo Chamoso, Roberto Casado-Vara, Alberto Rivas, Sigeru Omatu, and Juan M Corchado</i>	414
Mechanical Properties of Composites From Discarded Carpets <i>Adeayo Sotayo</i>	424
Polymer-Recycling of Bulk Plastics <i>Paul Thomas, Nelson P Rumjit, Chin W Lai, Mohd RB Johan, and Manickam P Saravanakumar</i>	432
The Potential of Core-Shell Technique in the Enhancement of Different Derived Calcium Carbonate Wastes in Anticorrosive Paints <i>NM Ahmed, WM Abd El-Gawad, and MG Mohamed</i>	455
Production of High Purity α - and γ -Alumina From Aluminum Dross <i>Mostafa Mahinroosta and Ali Allahverdi</i>	473
Recycled Ceramics in Concrete <i>César Medina Martínez, Isabel F Sáez del Bosque, Eloy Asensio de Lucas, Laura Caneda-Martínez, Moisés F Rojas, and María Isabel Sánchez de Rojas Gómez</i>	483
Recycling Aluminosilicate Industrial Wastes Into Geopolymer: A Review <i>Ali Allahverdi and Mostafa Mahinroosta</i>	490
Recycling Approaches, Policies and Regulations on Electronic Waste With Special Focus on India <i>Anwesha Borthakur and Pardeep Singh</i>	508
Recycling of Agricultural Waste for Wastewater Treatment <i>Rohini Singh</i>	514
Recycling of Construction and Demolition Wastes Into Renewable Construction Materials <i>Soon P Yap, Yingxin Goh, Kim H Mo, and Hussein A Ibrahim</i>	520
Recycling of E-Waste <i>Anwesha Borthakur and Pardeep Singh</i>	527
Recycling of Flax Fiber Towards Developing Biocomposites for Automotive Application From a Life Cycle Assessment Perspective <i>Yansong Guo and Yelin Deng</i>	535
Recycling of Lithium From Li-ion Batteries <i>Bhuvaneshwari Balasubramaniam, Narendra Singh, Swati Verma, and Raju K Gupta</i>	546
Recycling of Plastics for Low Cost Construction <i>Muyiwa Oyinlola and Timothy Whitehead</i>	555
Recycling of Red Mud for Value-Added Applications: A Comprehensive Review <i>Mostafa Mahinroosta, Zahra Karimi, and Ali Allahverdi</i>	561
Recycling of Renewable Composite Materials in the Offshore Industry <i>Chiemela V Amaechi, Charles O Agbomerie, Adeayo Sotayo, Facheng Wang, Xiaonan Hou, and Jianqiao Ye</i>	583
Smart Contract for Monitoring and Control of Logistics Activities: Garbage Utilities Case Study in a Smart City <i>Roberto Casado-Vara, Alfonso González-Briones, Javier Prieto, and Juan M Corchado</i>	614
Sustainable Geo-Materials in Construction Towards Climate Change Adaptation <i>Hemanta Hazarika, Siavash MK Pasha, Gopal SP Madabhushi, and Stuart K Haigh</i>	619
Synthesis of Multiwalled Carbon Nanotubes (MWCNTs) From Waste Cooking Oil Catalyzed by Mill-Scale Waste for Development of Microstrip Patch Antenna (MPA) <i>Ismayadi Ismail, Intan H Hasan, Zulkifly Abbas, Mohd N Hamidon, Muhammad S Mustaffa, and Nor H Abdullah</i>	635

The Utilization of Vegetable Fibers in Cementitious Materials <i>Oussama Benaïmeche, Nadhir Toubal Seghir, Łukasz Sadowski, and Mekki Mellas</i>	649
Utilization of Waste Expanded Glass in Cement Composites <i>Damian Stefaniuk and Łukasz Sadowski</i>	663
Valorization of Marble Waste in Cement-Based Materials <i>Nadhir Toubal Seghir, Łukasz Sadowski, Oussama Benaïmeche, and Mekki Mellas</i>	670
Biodegradable and Biobased Materials	
Bio-Based Materials in Sportswear Applications <i>Jane E Wood</i>	683
Biodegradable Packaging Materials <i>Ishrat Majid, Mamta Thakur, and Vikas Nanda</i>	688
Bioresorbable Polymers for Surgical Suture Applications <i>Radhika Vaid, Melissa A Pasquinelli, and Martin W King</i>	698
Bio-Waste Based Nanofiber Materials <i>Suman Sinha-Ray</i>	715
Developing Successful Biobased Product: Key Design and Manufacturing Challenges <i>Sweety Shahinur, AMM Sharif Ullah, and Mahbub Hasan</i>	727
The Effect of CaCO ₃ Nanoparticles and Chitosan on the Properties of PLA Based Biomaterials for Biomedical Applications <i>Md S Islam, Md M Islam, and Kh N Islam</i>	736
Injected Mold HDPE/Nanoclay Composite Products: Mechanical Properties and Quality <i>Mohd H Othman</i>	746
Jute/Coir/Banana Fiber Reinforced Bio-Composites: Critical Review of Design, Fabrication, Properties and Applications <i>Sweety Shahinur and Mahbub Hasan</i>	751
Kenaf Fiber Based Bio-Composites: Processing, Characterization and Potential Applications <i>Md S Islam, Md M Rahman, and Mahbub Hasan</i>	757
Materials Selection Charts for Designing Products With Biocomposites <i>Darshil U Shah</i>	768
Nanomaterial Based Sustainable Thermal Management <i>Suman Sinha-Ray</i>	781
Natural Fiber and Synthetic Fiber Composites: Comparison of Properties, Performance, Cost and Environmental Benefits <i>Sweety Shahinur and Mahbub Hasan</i>	794
Natural Indigo for Textiles: Past, Present, and Future <i>Mohammad A Uddin and Abu SM Sayem</i>	803
Opportunities With Renewable Jute Fiber Composites to Reduce Eco-Impact of Nonrenewable Polymers <i>MM Alamgir Sayeed, Abu SM Sayem, and Julfikar Haider</i>	810
An Overview on the Development of Natural Renewable Materials for Textile Applications <i>Abu SM Sayem and Julfikar Haider</i>	822
An Overview on the Opportunities for 3D Printing With Biobased Materials <i>Abu SM Sayem, Hasan Shahariar, and Julfikar Haider</i>	839

Palm Oil Fuel Ash: Innovative Potential Applications as Sustainable Materials in Concrete <i>Timothy ZH Ting, Matthew ZY Ting, Muhammad E Rahman, and Vikram Pakrashi</i>	848
Polysaccharide-Based Flocculants for Industrial Effluents <i>Kunal K Chandan and GP Karmakar</i>	858
Potentials of Natural Dyes for Textile Applications <i>Israt Zerin, Nawshin Farzana, Abu SM Sayem, Daniel M Anang, and Julfikar Haider</i>	873
3D Printing of Carbon-Based Conductive Materials for Electrochemical Energy Storage (EES) Application <i>Hasan Shahariar, Nipa Khair, and Rashedul Islam</i>	884
Processing, Properties and Prospects of Nano-Biocomposites <i>Mohd H Othman</i>	895
Renewable Energy Production From Environmental Hazardous Palm Oil Mill Waste Materials: A Review <i>Mollah I Shahidul, Mussen L Malcolm, Shahnur Begum, Mohamad SJ Hashmi, Mohamad S Islam, and JJ Eugene</i>	902
Wound Care: A Material Solution <i>Mohammad F Hossain</i>	915

VOLUME 3

Renewable and Sustainable Materials in Automotive and Consumer Products and Packaging

Application of Nanofluids for Radiator Cooling <i>Sudhakar Subudhi and Aditya Kumar</i>	1
An Assessment of Hydrogen Energy Utilization for Sustainable Development <i>Ahmet Z Sahin</i>	10
Bacterial Cellulose Based Nanocomposites for Electronic and Energy Applications <i>Sreeja K Sathish and Satish Vitta</i>	16
Biodegradable Packaging <i>Rajinder K Dhall and Mohammed S Alam</i>	26
Bio-Polymeric Packaging Material for Packaging of Raw Food <i>Sasmita Majhi, Anju Tyagi, and Abhijit Mishra</i>	44
CO ₂ Capture, Storage, and Enhanced Oil Recovery Applications <i>Muhammad Sagir, Muhammad Mushtaq, Muhammad S Tahir, Muhammad B Tahir, Sami ullah, Naeem Abbas, and Muhammad Pervaiz</i>	52
Development of Self-Adhesive Products Using Only Bamboo Fibers Extracted With a Machining Center <i>Keiji Ogawa, Toshiki Hirogaki, Eiichi Aoyama, and Hiromichi Nobe</i>	59
Effect on Compounding Process in Natural Rubber for Sustainable Suspension Materials <i>Mohd A Salim, Adzni M Saad, and Intan RA Rosszainily</i>	71
Experimental Investigations for Friction Stir Welded 3D Printed Dissimilar Thermoplastics With Consumable Tool <i>Ranvijay Kumar, Rupinder Singh, and Inderpreet S Ahuja</i>	79
Impact Behaviors of Acrylonitrile Butadiene Styrene and Polylactic Acid Materials for Topological Industries <i>Mohd A Salim, Adzni M Saad, and Zarif H Termiti</i>	83

Joining of 3D Printed Dissimilar Thermoplastics With Consumable Tool Through Friction Stir Spot Welding: A Case Study <i>Ranvijay Kumar, Rupinder Singh, and Inderpreet S Ahuja</i>	91
Joining of 3D Printed Dissimilar Thermoplastics With Friction Welding: A Case Study <i>Ranvijay Kumar, Rupinder Singh, Inderpreet S Ahuja, and Kamal N Karn</i>	97
Joining of 3D Printed Dissimilar Thermoplastics With Nonconsumable Tool Through Friction Stir Welding: A Case Study <i>Ranvijay Kumar, Rupinder Singh, and Inderpreet S Ahuja</i>	109
Mechanical and Transmissibility Effect on Recyclable Suspension System for Different Loading of Carbon Black <i>Mohd A Salim, Adzni M Saad, and Intan RA Rosszainily</i>	114
Natural Oils as Green Lubricants in Forming Processes <i>Abdulaziz S Alaboodi</i>	122
Natural Oils as Green Lubricants in Machining Processes <i>Sounak K Choudhury and Muhammed Muaz</i>	129
Oil Palm Kernel Shell – A Potential Sustainable Construction Material <i>Timothy ZH Ting, Muhammad E Rahman, Hieng H Lau, Matthew ZY Ting, and Vikram Pakrashi</i>	137
Recyclability of Packaging Materials for Domestic Applications <i>Kamaljit S Boparai and Rupinder Singh</i>	144
Recycled Polypropylene-Nanoclay Composites – Mechanical Properties <i>Mohd H Othman</i>	149
Recycling and Downstream Processing of Aluminium Alloys for Automotive Applications <i>Brij K Dhindaw, Gowrawaram SL Aditya, and Animesh Mandal</i>	154
Renewable and Sustainable Materials in Automotive Industry <i>Manojit Ghosh, Arkajit Ghosh, and Avinava Roy</i>	162
Renewable Biofuels and Their By-Products for Automotive Applications <i>Shailendra K Shukla</i>	180
A Review of the Value-Added Chemicals and Materials From Bio-Based Lignin Feedstocks <i>Maryam Akbari, Adetoyese O Oyedun, and Amit Kumar</i>	187
Sustainable Air-Conditioning <i>Rehan Khan, Ritunesh Kumar, and Nirupam Rohatgi</i>	201
Toward Reclamation of Fibrous Waste Stream Materials <i>Marlann M Patterson</i>	219
Utilization of Bio-Hydrogen in HCCI Engines as a Most Renewable Fuel for Sustainable Transportation – A Thermodynamic Analysis <i>Abdul Khaliq, Faizan Ahmad, and Faizan Khalid</i>	224
Mitigating Greenhouse Effect and Carbon Footprint Through Renewability Approach	
Advanced Vehicle Systems and Technologies: Economic and Environmental Implications <i>Trina Dutta and Gautam Majumdar</i>	232
Advances in Surface Engineering for Improved Energy Storage <i>Rishav K Baranwal, Nisantika Biswas, Buddhadeb Oraon, and Gautam Majumdar</i>	245
Alternate Photovoltaic Material: Its Environmental Consequences <i>Soumitra Kar and Sunanda Dey</i>	250

Application of Remote Sensing in Wind Resource Assessment <i>Siraj Ahmed and Prem K Chaurasiya</i>	265
Biomass for CO ₂ Sequestration <i>Andrew C Eloka-Eboka, Joseph K Bwapwa, and Semakula Maroa</i>	277
Carbon Capture and Storage (CCS) Technology: Challenges to Implementation <i>Zaharaddeen N Garba and Ahmad Galadima</i>	291
Carbon Footprint Reduction Instrument <i>Sk M Haque, Abhishek Das, and Rukhsana</i>	300
Carbon Management and Greenhouse Gas Mitigation <i>Anand Giri and Deepak Pant</i>	312
Catalytic Conversion of Greenhouse Gases <i>Osarieme U Osazuwa and Chin K Cheng</i>	336
Challenges of Employing Renewable Energy for Reducing Greenhouse Gases (GHGs) and Carbon Footprint <i>Chandan K Chanda and Dipanjan Bose</i>	346
Clean Energy Technologies: Hydrogen Power and Fuel Cells <i>Sameer Lamichaney, Rishav K Baranwal, Saikat Maitra, and Gautam Majumdar</i>	366
CO ₂ Sequestration Using Algal Biomass and its Application as Bio Energy <i>Ranjana Das, Swati Das, and Chiranjib Bhattacharjee</i>	372
Co-Firing of Biomass to Reduce CO ₂ Emission <i>Chanchal Loha, Himadri Chattopadhyay, Pradip K Chatterjee, and Gautam Majumdar</i>	385
Design and Synthesis of New Ruthenium Coordination Complex as Efficient Dye in DSSC Like Alternative Energy Resources With a Bird's Eye View on Strategies Towards GHGs Mitigation <i>Sourav Bej, Pritam Ghosh, Gautam Majumdar, Naresh C Murmu, and Priyabrata Banerjee</i>	395
Development of Vapor Absorption Cooling System Driven by Renewable Energy <i>Binoy K Choudhury, Avishek Ray, and Devashish (Dave) Lahiri</i>	411
Eco-Sustainable Molecular Quantum Dot Cellular Automata Based Radiography in Defect Identification of Industrial Product Using Renewable Energy Source <i>Paramartha Dutta and Debarka Mukhopadhyay</i>	437
Fermentative Production of Optically Pure Lactic Acid From Renewable Materials <i>Shubhalakshmi Sengupta, Papita Das, and Siddhartha Datta</i>	447
Gasification of Hospital Waste by Thermal Plasma: A Relevant Technology Towards Mitigation of Greenhouse Gases in India <i>Abhijit Hazra, Saikat Das, Pradip K Chatterjee, Amit Ganguly, and Priyabrata Banerjee</i>	454
Geological Storage of CO ₂ to Reduce Greenhouse Gases <i>Ramesh K Agarwal</i>	463
Green and Sustainable Manufacturing of Metallic, Ceramic and Composite Materials <i>Trina Dutta, Ananya Barman, and Gautam Majumdar</i>	474
Green Fuel Blending: A Pollution Reduction Approach <i>Rajat Chakraborty and Punam Mukhopadhyay</i>	487
Green Manufacturing: Progress and Future Prospect <i>Abhishek Das, Rukhsana, and Paramita Chatterjee</i>	501
Green Mining of Rare Earth Elements (REE) to Diminish Greenhouse Gas (GHG) Footprint <i>Ratna Dutta</i>	513

Hybrid Renewable Multigeneration: Low Carbon Sustainable Solution With Optimum Resource Utilization <i>Avishek Ray and Sudipta De</i>	526
Innovations in Variable Frequency Drives and its Implication in Reducing Carbon Footprint <i>Jitendra Saxena, Binoy K Choudhury, and Krishna M Agrawal</i>	534
Is the Production of Biofuels Environmentally Sustainable? <i>Lucas Reijnders</i>	545
Low Carbon Economy for Sustainable Development <i>Piyali Sengupta, Binoy K Choudhury, Sarbani Mitra, and Krishna M Agrawal</i>	551
Manufacturing of Biodegradable Poly Lactic Acid (PLA): Green Alternatives to Petroleum Derived Plastics <i>Shubhalakshmi Sengupta, Suwendu Manna, Uttariya Roy, and Papita Das</i>	561
Nanofluid in Energy Harvesting and Related Applications <i>Dipanwita Mitra, Kalyan K Chattopadhyay, and Paramita Chattopadhyay</i>	570
Nanomaterial for CO ₂ Sequestration <i>Priya Banerjee, Aniruddha Mukhopadhyay, and Papita Das</i>	598
Nanomaterials for Alternative Energy <i>Soumitra Kar, Sunanda Dey, Sovan Chakraborti, and Gautam Majumdar</i>	606
Optimal Operation of Renewable Distributed Generators (DGs) and its Environmental Benefits <i>Chandan K Chanda and Dipanjan Bose</i>	619
Overview of CCS: A Strategy of Meeting CO ₂ Emission Targets <i>Kuntal Jana and Sudipta De</i>	628
Plasma Arc Driven Solid Waste Management: Energy Generation and Greenhouse Gases (GHGs) Mitigation <i>Abhijit Hazra, Saikat Das, Gautam Majumdar, Naresh C Murmu, and Priyabrata Banerjee</i>	640
Polygeneration as Efficient and De-Carbonized Energy Solution <i>Kuntal Jana and Sudipta De</i>	655
Power and Other Energy Utilities From Low Grade Waste Heat – Novel Technologies to Reduce Carbon Footprint <i>Subha Mondal and Sudipta De</i>	667
Quality of Environment and Clean Manufacturing <i>Sameer Lamichaney, Rishav K Baranwal, Swapan K Maity, and Gautam Majumdar</i>	678
Reducing Greenhouse Gas Emission From Waste Landfill <i>Rena, Shashi Arya, Digambar Chavan, Sadaf Aiman, and Sunil Kumar</i>	685
Renewability Assessment of a Production System <i>Sandip Ghosh</i>	702
Renewable Biomass: A Candidate for Mitigating Global Warming <i>Chanchal Loha, Malay K Karmakar, Himadri Chattopadhyay, and Gautam Majumdar</i>	715
Renewable Electricity Generation – Effect on GHG Emission <i>Avishek Ray and Sudipta De</i>	728
Renewable Jet-Fuel (RJF): Mitigation of Aviation-Related GHG Emission <i>Rajat Chakraborty and Ritika Samanta</i>	736
Selected Issues in Economics of Greenhouse Gas Emission Mitigation <i>Shyamasree Dasgupta, Debrupa Chakraborty, and Joyashree Roy</i>	743

Solar Geoengineering <i>K Harish Kumar and Malay K Karmakar</i>	751
Sustainable Carbon Di-Oxide Sequestration Using Photosynthetic Reactions <i>Trina Dutta, Sangita Bhattacharjee, and Jit Chakraborty</i>	759
The Applicability of the Inflection Point in the Environmental Correction Process <i>Daniel Balsalobre-Lorente, Muhammad Shahbaz, Aviral K Tiwari, and Jose C Jabbour</i>	771
Thermoelectric Materials: Improving Energy Efficiency and Decreasing CO ₂ Emissions <i>Diptonil Banerjee and Kalyan K Chattopadhyay</i>	780
Traditional Biomass: A Replacement for Petro-Fuels <i>Ranjana Das, Banashree Samanta, and Chiranjib Bhattacharjee</i>	795
An Ultra Low Power Molecular Quantum Dot Cellular Automata Based X-ray (QX-ray) Generating System Using Renewable Energy Source <i>Paramartha Dutta and Debarka Mukhopadhyay</i>	810
Use of Clean, Renewable and Alternative Energies in Mitigation of Greenhouse Gases <i>Ratna Dutta</i>	821
Utilizing the Greenhouse Effect as a Source to Produce Renewable Energy <i>Abhishek Khapre, Anoop Jaiswal, Rena, and Sunil Kumar</i>	835
Wind Farm Repowering Using WAsP Software – An Approach for Reducing CO ₂ Emissions in the Environment <i>Manoj Verma</i>	844

VOLUME 4

Renewable Materials in Building, Construction, and Architecture

Analysis of the Thermal Performance and Comfort Conditions of Vernacular Rammed Earth Architecture From Southern Portugal <i>Jorge Fernandes, Sandra M Silva, Ricardo Mateus, and Elisabete R Teixeira</i>	1
Architecture Follows the Sun: Climatically Responsive Architecture and Process of Design <i>Arvind Krishan</i>	11
Bamboo Structural Technology <i>Sanjay Prakash and Divya Chand</i>	35
Conservation of Material, Technology and Practice in Heritage Structure and its Relevance in Today's Context <i>Apoorva Dandge and Sheeba Valsson</i>	39
Constructing a PV-Integrated Permanent Bamboo Building – An Experience <i>Madhumita Roy and Saroj Mandal</i>	50
Energy Efficiency and Thermal Comfort in Heritage Buildings <i>Anjali K Sharma</i>	58
Environmental Life Cycle Analysis of Earthen Building Materials <i>Ricardo Mateus, Jorge Fernandes, and Elisabete R Teixeira</i>	63
Evaluating the Sustainability Performance of Building Systems and Technologies for Mainstreaming Sustainable Social Housing in India <i>Rajat Gupta, Sanjoli Tuteja, Sanjay Seth, Megha Behal, Zeenat Niazi, Pratibha Caleb, Jesús S Villanueva, and Ayushman Banerjee</i>	69

Evaluation of Sustainability Indicators of Buildings <i>Anjali K Sharma</i>	87
Expediting Faster Housing Supply in India Using Straw Bale as Prefab Building Material <i>Monika S Gupta, Uttam K Roy, and Madhumita Roy</i>	92
Improving Building Technologies With a Sustainable Strategy <i>Jayashree Deshpande</i>	102
Improving Energy Efficiency in Buildings Through Responsible Design: Optimizing Use and Careful Selection of Building Materials <i>Madhumita Roy and Bharati Mohapatra</i>	110
Insulation Materials for the Building Sector: A Review and Comparative Analysis <i>Marco Casini</i>	121
LCCA and Environmental Impact of Buildings <i>Hina Zia</i>	133
Leadership in Energy and Environmental Design Rating System: A Global Tool to Assess Sustainability in Buildings, Communities and Cities <i>Mili Majumdar</i>	144
Life Cycle Assessment Methods and Procedures and Their Role in Measuring the Sustainability Component of a Construction Technology <i>Ujwala Chakradeo and Tarika Mohite Dagadkar</i>	158
Material Culture and Sustainability: Traditional Versus Modern in a Case of Northeast India <i>Mainak Ghosh and Farha Shermin</i>	167
Retrofitting of Buildings/Built Environment – A Sustainable Development Model <i>Anjan Mitra and Saptarshi Mitra</i>	179
Roof Gardens to Vertical Farming <i>Abraham George</i>	199
Study of Junctions With Bamboo: An Attempt Towards Their Classification <i>Rajarshi Ray and Parthasarathi Mukhopadhyay</i>	205
Sustainability and Green Building Rating Systems: A Critical Analysis to Advance Sustainable Performance <i>Laura Florez</i>	211
Sustainability of Advanced Materials in Construction <i>Marco Casini</i>	221
Sustainable Architecture, Alternative Concepts and Waste Reduction <i>Abraham George</i>	232
Thermal Adaptation and Sustainable Housing in Cold Climates <i>E Rajasekar, Ghanshyam Thakur, and Belay Zeleke</i>	244
Traditional Crafts as Materials in Placemaking: Application and Sustainability in Aesthetic Transformation of Geometry of Urban Public Spaces <i>Jayati Mukherjee and Mainak Ghosh</i>	259
Understanding High Performance Buildings: The Link Between Occupant Knowledge of Passive Design Systems, Corresponding Behaviors, Occupant Comfort and Environmental Satisfaction <i>Mili Majumdar</i>	292
Use of Lime Mortar and Post-Occupancy Thermal Performance Analysis of Buildings <i>Mona Doctor-Pingel and Vishnu Vardhan</i>	302

Use of Steel as a Sustainable Concept <i>Anjan Mitra</i>	315
Using Construction and Demolition Waste as Construction Materials for a New Building <i>Madhumita Roy</i>	330
Sustainable Materials and Technologies	
Advanced Polymeric Coatings and Their Applications: Green Tribology <i>Pixiang Lan, Emerson E Nunez, and Andreas A Polycarpou</i>	345
Application of Life Cycle Assessment for Sustainability Evaluation of Transportation Fuels <i>Najmul Hoque, Ilyas Mazhar, and Wahidul Biswas</i>	359
Biochar Production From Biomass Waste-Derived Material <i>Asfaw G Daful and Meegalla R Chandraratne</i>	370
Biocompatible Thermoplastic Composite Blended With HAP and CS for 3D Printing <i>Nishant Ranjan, Rupinder Singh, and Inderpreet S Ahuja</i>	379
Characterization and Interface of Natural and Synthetic Hybrid Composites <i>A Atiqah, M Chandrasekar, T Senthil Muthu Kumar, K Senthilkumar, and Mohamed NM Ansari</i>	389
Characterization and Phase Diagram of the Tetragonal Tungsten Bronze Type Ferroelectric Compounds $\text{Pb}_{2(1-x)}\text{Gd}_x\text{K}_{1+x}\text{Nb}_5\text{O}_{15}$ for Energy Storage Applications <i>Yaovi Gagou, Yassine Amira, Nadir Aliouane, Aimad Belboukhari, Billal Allouche, Abderrahim Menny, Jean-Luc Dellis, Daoud Mezzane, Mimoun El Marssi, Christian Masquelier, Matthieu Courty, Mohamed Elaati, and Pierre Saint-Grégoire</i>	401
Conversion of Renewable and Food Wastes Into Useful Products with Environmental Perspectives <i>Mohammad R Kasaai</i>	413
Energy Storage Device From Polymeric Waste Based Nano-Composite by 3D Printing <i>Rupinder Singh and Ranvijay Kumar</i>	425
Green and Healthy Alkaline Materials <i>Souad Al-Bat'hi</i>	433
Heat Affected Zone Morphology of TIG Torch Welded HSLA Steel in Presence of Ti and V Microalloying Elements <i>Moh HA Musa, Md Abdul Maleque, and Mohammad Y Ali</i>	439
Historical Development of Hybrid Materials <i>Mohd RBM Rejab, Mohammad HBM Hamdan, Ma Quanjin, Januar P Siregar, Dandi Bachtiar, and Yusrizal Muchlis</i>	445
Interface Study of $\text{SiC}_p/6061\text{Al}$ Composite <i>Adetayo A Adebisi, Md Abdul Maleque, and Kamilu A Bello</i>	456
Life Cycle Assessment in Buildings: An Overview of Methodological Approach <i>Grace KC Ding</i>	462
Lifecycle Assessment of Building Materials – A Cradle-to-Gate Approach <i>Grace KC Ding</i>	476
Life Cycle Cost Analysis for Green Buildings <i>IMCS Illankoon, Vivian WY Tam, and Khoa N Le</i>	489
Nickel Chromium Based Partial Denture Preparation: Conventional vs Additive Manufacturing Techniques <i>Gurpartap Singh, Rupinder Singh, and Sarbjit Singh</i>	500

Particulate Composite Protective Coating Using Conventional Melting Approach <i>Md Abdul Maleque, Nazrin Idris, Mohammad M Rahman, and Mohammad S Hossain</i>	510
Preparation of Partial Denture With Nano HAp-PLA Composite Under Cryogenic Grinding Environment Using 3D Printing <i>Nishant Ranjan, Rupinder Singh, and Inderpreet S Ahuja</i>	517
Processing of Ceramic Composite Coating via TIG Torch Welding Technique <i>Kamilu A Bello, Md Abdul Maleque, and Adetayo A Adebisi</i>	523
Removal of Chromium With CNT Coated Activated Carbon for Waste Water Treatment <i>Nassereldeen A Kabbashi, Abdurahman H Nour, Ma'an Al-Khatib, and Md Abdul Maleque</i>	536
Residual Stress Analysis for Sustainable Structural Integrity Assessment of an Engineering Component <i>Mohammad S Hossain and Md Abdul Maleque</i>	548
Solid Polymer Waste Materials for Repairing of Heritage Composite Structure: An Additive Manufacturing Approach <i>Rupinder Singh and Ranvijay Kumar</i>	557
Statistical Analysis of Energy Absorption in Aluminum Foam Sandwich Under Impact Testing Using the Taguchi Design <i>Muataz HF Al Hazza, Amalina Endut, Erry YT Adesta, Nur AB Ibrahim, and Mohammad Y Ali</i>	563
Structural, Thermal, Mechanical and Rheological Properties of Polylactic Acid/Epoxidized Soybean Oil/Organoclay Blends <i>Fathilah B Ali, Hazleen Anuar, and Jamarosliza Jamaluddin</i>	569

Advent of an Agro Friendly Approach in Bangladesh

Mohammad Abu Sadeque, Tamanna Rahman, and Mohammad Tosnimul Hassan, Housing and Building Research Institute, Mirpur, Dhaka, Bangladesh

© 2019 Elsevier Inc. All rights reserved.

Introduction

The 21st century has fueled a kinetic phase for Bangladesh unknown at any previous time in history. Here the predominant agrarian economy is giving way to boosting an industrialized economy; rural grounds are experiencing urbanization at an unprecedented scale and pace. The current process of unplanned and unregulated developmental activities is taking its toll on its environment and limited natural resources.

Land, a fundamental resource base for agriculture, fisheries, industry, and other economic activities, and which provides human and natural habitat as well, is under constant threat of decline ([National Land Zoning Project](#), Ministry of Land, Government of Bangladesh). However, agricultural land in the country is decreasing at an alarming rate. Indiscriminate settlement and industrialization is aggravating land conversion hence reducing farm production, leading to national food shortage for an increasing population. Under the current trend of urbanization, industrialization, and river erosion, studies claim that Bangladesh is losing 1% of agricultural land or 82,900 hectares (ha) every year; 17% is due to burnt clay brick production and construction of brick kilns, whereas approximately 80% is due to unplanned and unregulated rural housing and the remaining 3% is for unchecked urbanization and industrialization. The customary building construction trend is another major contributor to this phenomenon. In Bangladesh construction usually focuses on the use of burnt clay bricks and reinforced concrete, which are not environment or agro friendly. It has been estimated that every year Bangladesh produces 18 billion burnt clay bricks using around 45 million tons of agricultural topsoil ([Bharadwaj and Bhattacharjee, 2015](#)), which is also responsible for 25% of total national greenhouse gas (GHG) emission. As per COP21, in its INDC Bangladesh pledged an unconditional 5% GHG emission cut by 2030. It is estimated that only an alternative to fired bricks can cut the emission by 10% within the next 5 years.

A very pertinent question in this context is whether the existing construction system has the potential to be improved and adapted to meet the perpetual extremities of nature and ever depleting natural resources. Owing to the rise of such challenging conditions, Bangladesh immediately requires a paradigm shift in the construction sector and stringent measures regarding rural settlement planning across its borders.

Housing and Building Research Institute (HBRI; an autonomous organization dealing with housing and settlement problems and operating under the Ministry of Housing and Public Works, Government of Bangladesh) is working in this regard in bringing innovation including alternatives to traditional bricks with a target of achieving zero use of agricultural topsoil for brick production, and standardization of new construction materials through research. As per the Government's 7th five-year plan, special emphasis is given for extension services of the institute to disseminate newly developed technologies and building materials that will be agriculture and environment friendly, disaster resilient, and affordable. HBRI is also working under the projected Government policy of saving agricultural land stock and acting as a crucial player in developing design and planning schemes for multistory residence-based sustainable suburban/rural settlements. Development and application of ferrocement technology as an alternative to traditional RC construction as structural, infill, and roofing element; and multiple alternative blocks, for example, sand-cement block, thermal block, compressed stabilized earthen blocks from river-dredged soil, etc. are some of the emerging alternative materials that make up many of HBRI's research initiatives.

Therefore, the changed perception of sustainability in relevance of the new world context enables these activities of HBRI to attempt to step forward toward an agriculture friendly approach. This article showcases the outcomes of HBRI's applied research on alternative building material and its application in different sectors.

An Overview of Land Morphology in Bangladesh

Bangladesh is principally an agricultural country, characterized by rice paddy agriculture dominated landscapes. So, land resource is the major asset contributing wealth and livelihood in rural areas, although land-human ratio is very low, estimated to be 0.06 ha per person ([FAO, 2013](#)). The total area of Bangladesh has risen in the last few decades, i.e., an increase is noted from 144,873 km² in 1976 to 145,306 and 145,778 km² over the years of 2000 and 2010 respectively. The overall gain of land is 90,512 ha primarily due to accreted lands in the southern coastal zone ([Hasan et al., 2013](#)).

The land resource of the country is divided into two categories, i.e., agriculture lands and nonagriculture lands. However, a declining trend was observed for the total agricultural lands of the country, i.e., a decrease is noted from 91.83% in 1976 to 87.69% and 83.53% over the years of 2000 and 2010 respectively. A total of 561,380 ha agricultural lands was decreased during 1976–2000 and this number was increased to 565,370 ha during 2000–2010. Yearly average loss of agriculture lands was 23,391 ha and 56,537 ha during 1976–2000 and 2000–2010 respectively. The nonagriculture lands of the country were 8.17%, 12.31%, and 16.47% during 1976, 2000, and 2010, respectively. The extent of nonagriculture lands were increased by 2.13% and 3.43%

during 1976–2000 and 2000–2010, respectively. Annual land loss from crop agriculture is 68,700 ha, where land gained in rural settlement, urbanization and industry, and aquaculture is 30,809 ha, 4012 ha and 3216 ha, respectively, during 2000–2010 (Hasan *et al.*, 2013).

The shifting rate of agricultural land to nonagricultural use is said to be about 1% per year (Planning Commission, Ministry of Planning, Bangladesh, 2009), which is alarming in respect to the total crop production and food security in Bangladesh (Rahman and Hasan, 2003). The Soil Resource Development Institute (SRDI), Ministry of Agriculture, estimated approximately 0.13% land transfer from agriculture to nonagriculture sector per year during the period 1963 to 1983 (Rahman and Hasan, 2003). It is likely that the shifting rate may be much faster during the 2000s till date, because of faster economic growth and the infrastructure development implied (Hasan *et al.*, 2013).

Agricultural land has declined about 0.26% annually from 1976–77 to 2010–11 (34-year average), 0.42% annually from 1976–77 to 2000–01 (25-year average), 0.75% annually from 1983–84 to 1993–94 (10-year average) and 0.40% annually from 1993–94 to 2003–04 (10-year average). There is slight increase of agricultural land from 2000–01 to 2010–11 (average 0.14%) (Table 1). Rahman (2010) reported the overall land area of the country increased 4% during 1948 to 2006 due to reclamation of char lands and the cultivable land declined 0.10% annually, assuming transfer to housing, road, and industrial infrastructures. Total agricultural land reduced 1,126,750 ha during the past 34 years (1976–2010) with yearly average loss 33,140 ha. Data analysis reveals a rapid decreasing trend of agricultural land found during the period of 2000–2010 (Hasan *et al.*, 2013).

Average yearly agricultural land lost was 0.18%, 0.44%, and 0.25% during 1976–2000, 2000–10, and 1976–2010, respectively.

Agricultural land shifting rate is alarming because food security is the main economic and political concern of Bangladesh. Geospatial extent of cropland cover maps of Bangladesh are given in Fig. 1

Table 1 Availability of agricultural land from 1976–77 to 2010–11

Year	Land area of Bangladesh (million ha)	Cultivable land (million ha)	% Cultivable land
1976–77	14.28	9.39	65.75
1980–81	14.29	9.38	65.64
1985–86	14.48	9.44	65.19
1990–91	14.84	9.72	65.50
1995–96	14.84	8.72	58.76
2000–01	14.85	8.40	56.57
2005–06	14.84	8.42	56.74
2010–11	14.84	8.52	57.41

Source: Reproduced from Bangladesh Bureau of Statistics (BBS), 2011. Agricultural Census of Bangladesh. Dhaka: Ministry of Planning.

Note: Agricultural land is the summation of cropland, current fallow, and cultivable waste.

Fig. 1 Cropland maps of Bangladesh in the years of (a) 1976, (b) 2000, and (c) 2010, after satellite imagery interpretation. Reproduced from Hasan, M.N., Hossain, M.S., Bari, M.A., Islam, M.R., 2013. Agricultural Land Availability in Bangladesh, Soil Resource Development Institute (SRDI), Ministry of Agriculture.

Table 2 Total land area of Bangladesh, based on Landsat satellite data

Land cover type	1976		2000		2010	
	Area	% of total	Area	% of total	Area	% of total
Agricultural land	13,303,654	91.83	12,742,274	87.69	12,176,904	83.53
Nonagricultural land	1,183,605	8.17	1,788,307	12.31	2,400,867	16.47
Total	14,487,259	100	14,530,581	100	14,577,771	100

Source: Reproduced from Hasan, M.N., Hossain, M.S., Bari, M.A., Islam, M.R., 2013. Agricultural Land Availability in Bangladesh, Soil Resource Development Institute (SRDI), Ministry of Agriculture.

Nonagricultural land included rural settlement, brick kiln, urban and industrial estate, and accreted land. The nonagricultural land was estimated 1,183,605 ha; 1,788,307 ha and 2,400,867 ha, which correspond to 8.17%, 12.31%, and 16.47% during 1976, 2000, and 2010 respectively (**Table 2**). Maximum increasing of 612,560 ha was found during 2000–10, representing 0.42% yearly average increasing rate. Rural settlement area was estimated 885,637 ha in 1976 occupying 6.11% of the total area of the country. Rural settlement area consistently increased over time which grabbed 1,458,031 ha (10.03%) in 2000 and 1,766,123 ha (12.12%) in 2010. Yearly average increasing rate were 0.16% and 0.21% during 1976–2000 and 2000–10, respectively. The overall rate of increase in rural settlement was 0.18% during the 34-year period (1976–2010). Another driving force is urbanization and industrialization. The yearly increasing rate of urbanization and industrialization was higher (0.03%) during 2000–10, followed by 0.01% during 1976–2000. Yearly average 4012 ha land was transferred to urbanization and industrialization sector during 2000 to 2010.

Prevailing Construction Industry and Its Impact

The prevailing construction industry poses a major threat to our environment and agriculture.

Agricultural Impact

As per a report published in the national daily *The Daily Star*, heavy use of clay from agricultural land causes depletion of topsoil and acid deposits from brick kiln affect agricultural productivity (Roy and Roy, 2016). Various projects and initiatives have introduced technologies targeting to reduce GHG emission but traditional clay content, which requires burning, is still used in brick production. Up to 18 in. of topsoil is collected from a cropland whereas it loses its fertility even if only the top six inches of soil is removed. Farmers are often forced to sell topsoil to the owners of the brick kiln. The level of land adjacent to the kilns goes down when the owner sells the topsoil and then irrigation water cannot be held in other lands adjacent to those lands. This incident leaves no choice to the owners of these lands but to sell the topsoils eventually.

Brick kilns are destroying large areas of agricultural land every year, which increased into 5000 ha during the 1998 to 1999 period in different pockets of brick fields (Rahman and Khan, 2001). These affected areas are expanding rapidly due to the increase in brick production (IUSS, 2002). There are about 6000 brick manufacturers in Bangladesh, which produce about 18 billion pieces of brick a year consuming around 45 million tons of fertile soil – equivalent to around 2600 ha of agricultural land. At this rate, the country is quickly moving toward severe food shortages in the foreseeable future (Bharadwaj and Bhattacharjee, 2015). In addition, acid deposits from the sulfur dioxide (SO₂) and NO_x emitted from the brick kilns negatively affect agricultural productivity.

Environmental Impact

Construction impacts last for decades and affect the lives of current and future generations. Buildings consume major global resources. Almost 50% of global energy is consumed in buildings, while 50% water, 60% materials for buildings, 80% land loss to agriculture, 60% timber products, 90% hardwoods are all directly linked with building construction. Indirectly 50% of coral reef destruction and 25% of rain forest destruction are all attributed to buildings and construction (US Environmental Protection Agency). The brick industry emits 8.75 million tons of GHG annually and consumes 2.2 million tons of coal and 1.9 million tons of firewood annually. Around 30% of brick kilns use firewood illegally, aggravating deforestation (published in the national daily *The Independent* on 29 July, 2016).

The major impacts of construction are excessive energy use, global warming, and climate change. Energy is consumed when extracting raw materials, producing materials (manufacturing process), transporting materials, transporting workforce, building structures, using and powering structures, maintaining structures, and demolishing. In addition, energy is also required for the operation of any structure(s).

Approximately 120 million MT concrete, of which 10 million MT is water, 20 million MT is cement, and 90 million MT is aggregate, is used in Bangladesh. The total aggregate used in the world is 9 billion tonnes. So it is an important aspect in concrete

Table 3 CO₂ emission and energy consumption for building materials used in Bangladesh (construction phase only)

Sl.	Product description	Standard value per unit	
		CO ₂ emission (ton)	Energy consumption (GJ)
1	Cement (bags)	0.0194	0.0935
2	Brick (Nos)	0.00054	0.00575
3	Stone (cft)	0.00356	0.00483
4	Sand (cft)	0.00138	0.02346
5	Rebar (kg)	0.0000624	0.001365
6	Glass (kg)	0.0013	0.0184
7	Lime (ton)	0.47	5.69

Source: Reproduced from Alam, M.S., Ahmad, S.I., 2013. Analysis of life cycle environmental impact for residential building in Bangladesh. International Journal of Technology Enhancements and Emerging Engineering Research 2 (1), 1.

production and its production and transportation will emit carbon dioxide and consume fuel. So when using energy saving material, not sacrificing strength is important and locally available materials induce in concrete will help by the course (Alam and Ahmad, 2013). In case of clay burnt brick production, most of the CO₂ is produced during construction phase and huge amount of energy is consumed as well. In order to reduce CO₂ emission, we have to think of alternatives to conventional brick production methods. This table will encourage us to analyze more the environmental impact of building and will show the importance of reducing the emission of CO₂ (Table 3).

The concept of sustainable construction and green development incorporates and integrates a variety of strategies during the design, construction, and operation of building projects. The use of green building materials and products represents one important strategy in the design of a building. It needs to be understood that sustainable construction techniques are different than “good practices.” Green building materials are composed of renewable, rather than nonrenewable resources. Green materials are environmentally responsible because their environmental impacts are considered over the “life of the product” (Spiegel and Meadows, 1999).

Advent of a New Approach: Alternative Building Material and Construction Technology Developed by Housing and Building Research Institute

HBRI is an autonomous organization under the Ministry of Housing and Public Works, Government of Bangladesh, with a constitutional framework of a Governing Council headed by the Honorable Minister in charge of the Ministry. It runs by the allocation of Government grants from the revenue fund. Since the beginning, all the Divisions of the Institute rendered useful contributions in the field of housing. It renders extension services in the form of consultancy, laboratory testing, and planning pertaining to building activities in both public and private sectors. The Institute is the only national research institute that is entrusted to conduct research in housing problems, and innovation in construction materials, technology, and planning.

As per the Government’s 7th Five-Year Plan, HBRI will focus on bringing innovation including alternatives to traditional bricks with a target of achieving zero use of agricultural topsoil for brick production, and standardization of construction materials through research. Special emphasis will be given for extension services to disseminate newly developed technologies and building materials that will be agriculture and environment friendly, disaster resilient, and affordable. It will also continue updating the Bangladesh National Building Code (BNBC) and on a pilot basis steps will be taken for the construction of 75 low cost multistoried residential buildings in different villages during the 7th Plan period.

Regarding Bangladesh and COP21, in its Intended Nationally Determined Contributions (INDC) Bangladesh pledged an unconditional 5% GHG emissions cut by 2030, adding that with financing and technology support it will cut emissions by 15%.

As per Prime Minister’s Directives to HBRI, during her visit on 28 December 2014, to the Ministry of Housing and Public Works, the honorable Prime Minister provided some instructions:

- An intense initiative has to be undertaken to publicize the HBRI’s act of innovation regarding new building materials.
- Appropriate planning has to be drafted to properly utilize and apply the research outcomes.
- Ferrocement must be introduced in various housing and rural settlement development projects.
- Research initiative must be undertaken regarding construction of hollow blocks from river-dredged sand.
- Measures must be taken to produce environment-friendly bricks from river-dredged soil.

The United Nations’ Sustainable Development Goal 11: Sustainable Cities and Communities and Goal 13: Climate Action also falls in line with HBRI’s venture.

Addressing all the core issues, the main objective of HBRI can be summarized as:

- To conduct and promote action based technical research on alternative building material and construction technologies that are environment and agriculture friendly, disaster resilient, and cost effective.

With a target of achieving zero use of agricultural topsoil for brick production and standardization of new construction materials through research and dissemination, HBRI is continuously designing, developing, and upgrading different building materials and technologies. Several attempts have been taken as part of HBRI's noble venture in promoting an environment and agriculture friendly approach.

Given below is a list with detailed descriptions of alternative building materials and technologies and several examples of implemented and under-construction projects that have been developed with the alternative technologies by HBRI.

Wall Elements

Ferrocement

Specific feature (Fig. 2):

1. Raw Material
 - Cement
 - Sand
 - Wire mesh
 - MS bar

a)

b)

Fig. 2 Ferrocement wall. (a) cast-in-situ (source HBRI) and (b) precast. Data from Housing and Building Research Institute.

2. Engineering and physical properties

Cast-in-situ:

- Cement: sand = 1:2.
- Sylhet sand (FM 2.2–2.6)
- W/C = 0.45.
- Iron wire mesh = 2 layers of 18 BWG or 20 BWG with ½" opening.
- Skeleton MS Bar = 8 mm ϕ (both way) @ 2" c/c.

Precast

- Cement: sand = 1:2
- Sylhet sand (F.M 2.2–2.6)
- W/C = 0.38–0.45
- Iron wire mesh = 2 layers of 18 BWG or 20 BWG with ½" opening.
- Skeleton MS Bar = 8 mm ϕ (both way) @ 2" c/c.

Sandwich panel

Specific feature (Fig. 3):

1. Raw material

- Cement
- Sand
- Wire mesh
- MS bar
- Expanded polystyrene sheet (EPS)

2. Engineering and physical properties

- Total thickness of the concrete (cement:sand = 1:3) on interior and exterior faces = 25 mm
- Sylhet sand (FM 2.2–2.6)
- W/C = 0.45
- Iron wire mesh = 18 BWG with ½" opening
- Thickness of expanded polystyrene sheet (density = 15 kg/m³) = 56.25 mm
- Total finishing thickness = 87.5 mm

Sand-cement block (type I)

Specific feature (Fig. 4):

1. Raw material

- River-dredged soil/sand

Source: Brahmaputra River

Location: Jamalpur, Bangladesh

2. Physical properties

- Size: 400 × 200 × 100 mm³
- Weight: 9.5 kg

**Fig. 3** Sandwich Panel. Data from Housing and Building Research Institute.

Fig. 4 Sand-cement block (type I). Data from Housing and Building Research Institute.

Fig. 5 Sand-Cement Block (Type II: 3 Hole). Data from Housing and Building Research Institute.

3. Engineering properties
 - Compressive strength: 6 Mpa
 - Water absorption: <10%
4. Engineering economy
 - Economic w.r.t. burnt clay brick

Sand-cement block (type II: 3 hole)

Specific feature (Fig. 5):

1. Raw material
 - River-dredged soil/sand

Source: Feni River
Location: Chittagong, Bangladesh
2. Physical properties
 - Size: $400 \times 200 \times 100 \text{ mm}^3$
 - Weight: 9.5 kg
3. Engineering properties
 - Compressive strength: 30 Mpa
 - Water absorption: <5%
4. Engineering economy
 - Economic w.r.t. burnt clay brick

Fig. 6 Sand-cement block (type III: 11 Hole). Data from Housing and Building Research Institute.

Sand-cement block (type III: 11 hole)

Specific feature (Fig. 6):

1. Raw material
 - River-dredged soil/sand
- Source: Feni River
Location: Chittagong, Bangladesh
2. Physical properties
 - Size: $240 \times 175 \times 70 \text{ mm}^3$
 - Weight: 3.22 kg
 - Lightweight
3. Engineering properties
 - Compressive strength: 30 Mpa
 - Water absorption: <10%
4. Engineering economy
 - Economic w.r.t. burnt clay brick

Interlocking compressed stabilized sand block

Specific feature (Fig. 7):

1. Raw material
 - Cement: 10%, Coarse Sand: 90%
2. Physical properties
 - Size: $240 \times 175 \times 70 \text{ mm}^3$
 - Weight: 3.5 kg
 - Lightweight
3. Engineering properties
 - Water absorption: <10%.
4. Engineering economy
 - Economic w.r.t. burnt clay brick

Interlocking compressed stabilized earth block

Specific feature (Fig. 8):

1. Raw material
 - Cement 10%, River-dredged soil 90%

Fig. 7 Interlocking compressed stabilized sand block. Data from Housing and Building Research Institute.

Compressed stabilized earth block (type II)

Specific feature (Fig. 10):

1. Raw material
 - Cement (10%), River-Dredged Soil (90%), Jute Fiber

Source: Kopotakkho River

Location: Jessore, Bangladesh

2. Physical properties
 - Size: $240 \times 115 \times 76 \text{ mm}^3$
 - Weight: 4 kg
3. Engineering properties
 - Compressive strength: 4.7 Mpa
 - Water absorption: <10%
4. Engineering economy
 - Economic w.r.t. clay burnt brick

Compressed stabilized block with fly ash

Specific feature (Fig. 11):

Fig. 11 Interlocking compressed stabilized block with fly ash. Data from Housing and Building Research Institute.

1. Raw material
 - Cement 20%, fly ash 80%
2. Physical properties
 - Size: $240 \times 115 \times 76 \text{ mm}^3$
 - Weight: 2.5 kg
 - Lightweight
3. Engineering properties
 - Compressive strength: 3 Mpa
4. Engineering economy
 - Economic w.r.t. burnt clay brick

Aerated concrete block

Specific feature (Fig. 12):

1. Raw material
 - Cement, aluminum powder
2. Physical properties
 - Size: $254 \times 127 \times 127 \text{ mm}^3$
 - Weight: 3.2 kg
 - Lightweight
3. Engineering properties
 - Compressive strength: 2.5 Mpa
 - Water absorption: ~20%
4. Engineering economy
 - Economic w.r.t. burnt clay brick

Thermal block (two side mortar with key)

Specific feature (Fig. 13):

1. Raw material
 - Cement (25%), expanded polystyrene sheet, coarse sand (75%)
 - Source: local market
2. Physical properties
 - Size: $242 \times 114 \times 69 \text{ mm}$
 - Weight: 1.3 kg
 - Lightweight
3. Engineering properties
 - Compressive strength: 4.9 Mpa
 - Water absorption: <5%
 - Sand: FM: 2.5
4. Engineering economy
 - Economic w.r.t. burnt clay brick

Thermal block (four side mortar)

Specific feature (Fig. 14):

Fig. 12 Aerated concrete block. Data from Housing and Building Research Institute.

Fig. 14 Thermal Block (Four Side Mortar). Data from Housing and Building Research Institute.

1. Raw material
 - Cement (25%), coarse sand (75%),
 - expanded polystyrene sheet
 Source: local market
2. Physical properties
 - Size: $242 \times 114 \times 69 \text{ mm}^3$
 - Weight: 1.22 kg
 - Lightweight
3. Engineering properties
 - Compressive strength: 4.9 Mpa
 - Water absorption: <5%
4. Engineering economy
 - Economic w.r.t. burnt clay brick

Coconut coir board

Specific feature (Fig. 15):

1. Raw material
 - Cement (70%), coconut coir (30%)
2. Physical properties
 - Size: $600 \times 300 \times 25 \text{ mm}^3$
 - Lightweight
3. Engineering economy
 - Economic w.r.t. conventional interior

Roofing Elements

Precast ferrocement U-channel

Specific feature (Fig. 16):

1. Raw material
 - Cement, sand, wire mesh, MS bar
2. Physical properties
 - Width: 600 mm (including rib portions), length: 3800 mm (can be changed as per requirement)
 - Thickness:

Flange thickness: 25 mm

Rib thickness: 50 mm

3. Engineering economy
 - Economic w.r.t. conventional RC slab

Precast ferrocement folded plate

Specific feature (Fig. 17):

1. Raw material
 - Cement, sand, wire mesh, MS bar
2. Physical properties
 - Size:

Flange width: 125 mm

Thickness: 25 mm

Maximum depth: 150 mm

Length = Usually 3200 mm (can be changed as per requirement)

3. Engineering economy
 - Economic w.r.t. conventional RC slab

Precast ferrocement corrugated sheet

Specific feature (Fig. 18):

1. Raw material
 - Cement, sand, wire mesh, MS bar
2. Physical properties
 - Size:

Fig. 15 Coconut coir board. Data from Housing and Building Research Institute.

Fig. 16 Precast ferrocement U-channel. Data from Housing and Building Research Institute.

Flange width: 125 mm
 Thickness: 25 mm
 Maximum depth: 150 mm
 Length = Usually 3000 mm (can be changed as per requirement)

3. Engineering economy
 - Economic w.r.t. conventional RC slab

Precast ferrocement L-panel

Specific feature (Fig. 19):

1. Raw material:
 - Cement, sand, wire mesh, MS bar
2. Physical properties:
 - Size:

Rib depth: 125 mm
 Rib width: 50 mm
 Flange width: 530 mm

3. Flange thickness: 25 mm
 - Provision of 20–25 mm groove in the flange/top of the rib along the length is made for laps over the adjacent units.
4. Engineering economy:
 - Economic w.r.t. conventional RC slab

Fig. 17 Precast ferrocement folded plate. Data from Housing and Building Research Institute.

Fig. 18 Precast ferrocement corrugated sheet. Data from Housing and Building Research Institute.

Fig. 19 Precast ferrocement L-panel. Data from Housing and Building Research Institute.

Flooring Elements

Precast ferrocement floor tiles

Specific feature (Fig. 20):

1. Raw material
 - Cement, sand, wire mesh
2. Physical properties
 - Size: $600 \times 600 \times 25 \text{ mm}^3$
3. Engineering economy
 - Economic w.r.t. conventional floor tiles

Fig. 20 Precast ferrocement floor tiles. Data from Housing and Building Research Institute.

Fig. 21 Precast ferrocement column/beam. Data from Housing and Building Research Institute.

Structural Elements

Precast ferrocement column/beam

Specific feature (Fig. 21):

1. Raw material
 - Cement, sand, wire mesh, MS bar
2. Physical properties
 - Size: $125 \times 125 \text{ mm}^2$
 - Length: 3000–3600 mm
 - Hollow diameter: 75 mm
3. Engineering economy
 - Economic w.r.t. conventional RC column/beam

Precast ferrocement pile

Specific feature (Fig. 22):

1. Raw material
 - Cement, sand, wire mesh, MS bar

Fig. 22 Precast Ferrocement Pile. Data from Housing and Building Research Institute.

2. Physical properties
 - Size: $125 \times 125 \text{ mm}^2$
 - Length: 3000–3600 mm
 - Hollow diameter: 75 mm
3. Engineering economy
 - Economic w.r.t. conventional RC pile

Precast ferrocement footing

Specific feature (Fig. 23):

1. Raw material
 - Cement, sand, wire mesh, MS bar
2. Physical properties
 - Size: $1250 \times 1250 \text{ mm}^2$
 - Height: 900 mm
3. Engineering economy
 - Economic w.r.t. conventional RC footing

Miscellaneous Elements

Precast ferrocement louver

Specific feature (Fig. 24):

1. Raw material
 - Cement, sand, wire mesh, MS bar
2. Physical properties
 - Size: $37.5 \times 100 \times 2400 \text{ mm}^3$

Ferrocement irrigation drain

Specific feature (Fig. 25):

1. Raw material:
 - Cement, sand, wire mesh, MS bar
2. Physical properties:
 - Size: $1500 \times 600 \times 600 \text{ mm}^3$

Application of Alternative Building Material and Construction Technologies

HBRI is implementing the use of alternative building materials and construction technology in building different residential, administrative, and public built forms. Alternative building technology is being applied in different demonstration projects as well. A few of the examples are discussed below:

Multistoried House (Rural Type I)

Special Features (Fig. 26):

- Building type: residential
- Foundation: RC
- Beam and column: RC
- Floor and roof: ferrocement channel
- Ground floor: soil-cement stabilized
- Wall: ferrocement, 3D panel and sand-cement block
- Staircase: ferrocement
- Plinth area: 130 m²
- Status: completed
- Location: HBRI premises

Multistoried House (Rural Type II)

Special features (Fig. 27):

- Building type: residential
- Foundation: RC
- Beam and Column: RC
- Floor and roof: ferrocement channel
- Ground floor: soil-cement stabilized
- Wall: ferrocement/thermal block/sandwich panel

Fig. 27 Multistoried house (rural type II). Data from Housing and Building Research Institute.

- Staircase: ferrocement
- Plinth Area: 156 m²
- Status: This design has been developed as part of HBRI's venture in formulating the Standard Guideline and Design for Rural Housing in Disaster Prone Areas of Bangladesh.

Precast Prefabricated Stilt House for Ethnic Community

Special features (Fig. 28):

- Building type: residential
- Foundation: ferrocement pocket footing
- Beam and column: ferrocement precast beam and column
- Floor: ferrocement channel
- Roof: ferrocement corrugated sheet
- Ground floor: soil-cement stabilized
- Wall: plastered bamboo matt
- Ladder: wooden
- Plinth area: 19 m²
- Status: completed
- Location: HBRI Premises and piloting in Borguna, Bangladesh as part of a Government project.

Display Center

Special features (Fig. 29):

- Building type: public facility
- Foundation: RC
- Beam and column: RC
- Floor: ferrocement channel
- Ground floor: soil-cement stabilized

Fig. 28 Precast prefabricated stilt house. Data from Housing and Building Research Institute.

- Roof: ferrocement folded plate
- Wall: sandwich panel and thermal block
- Plinth area: 650 m²
- status: under construction
- Location: HBRI Premises

Training Center

Special features (Fig. 30):

- Building type: institutional
- Foundation: RC
- Beam and column: RC
- Floor and roof: ferrocement channel
- Ground floor: soil-cement stabilized
- Floor tiles: ferrocement
- Wall: CLC block and sandwich panel
- Plinth Area: 375 m²
- Status: under construction
- Location: HBRI premises

Public Toilet and Waiting Facility

Special features (Fig. 31):

- Building type: public utility
- Foundation: ferrocement pocket footing
- Beam and column: ferrocement
- Floor: soil-cement stabilized
- Roof: ferrocement corrugated sheet and ferrocement channel
- Wall: ferrocement, thermal block
- Plinth area: 135 m²

Fig. 29 Display center. Data from Housing and Building Research Institute.

Fig. 30 Training Center. Data from Housing and Building Research Institute.

- Status: construction will initiate soon
- Location: HBRI premises

Innovative Projects by HBRI in Collaboration With National and International Bodies

HBRI has joined to different organizations to work in close collaboration regarding the research, implementation, and dissemination of alternative building material and construction technologies.

Standard Guideline and Design for Rural Housing in Disaster Prone Areas of Bangladesh

Bangladesh is predisposed to numerous natural extremities due to its geographic location and meteorological features. Every year the country faces multiple exposures to extreme natural phenomena that significantly affect the overall livelihood of the

Fig. 31 Public toilet and waiting facility: (a) perspective view and (b) elevation. Data from Housing and Building Research Institute.

inhabitants. Predominantly housing is the most affected paradigm, facing the utmost adverse impacts of nature. Although Bangladesh has shown responsive approaches to disaster risk reduction and management, lack of an inclusive policy and guideline at a national level is obstructing the successful outcome of the overall process in most of the cases. In order to address the greater need of the nation, an inevitable demand has been felt to formulate a national guideline and design a manual for rural areas, especially areas prone to natural extremes. The aim of formulating this design guideline is to assist both the housing facilitators and end users living in extreme natural conditions (Fig. 32).

The project Standard Guideline and Design for Rural Housing in Disaster prone areas of Bangladesh was hosted by the Department of Disaster Management under the Ministry of Disaster Management and Relief, Bangladesh, in collaboration with HBRI under the Ministry of Housing and Public Works. A consultancy firm from Bangladesh, GHORAMIJON, which focuses mostly on development of sustainable, resilient and ecologically responsive habitat and settlements of marginalized communities who hardly gain any technical assistance from mainstream practitioners in dealing prevailing socioenvironmental crises, acted as the architectural, environmental, and climatic design consultant in designing and developing the design catalogue for the project. It was supported and comoderated by Friendship and IFRC Shelter Research Unit and sponsored by the Government of the Grand Duchy of Luxembourg and Friendship Luxembourg.

Promoting Sustainable Building in Bangladesh

Oxfam in partnership with Housing and Building Research Institute (HBRI), Bangladesh Environmental Lawyers Association (BELA), and Jagorani Chakra Foundation (JCF), have initiated actions to generate market transformation for alternative bricks (AB) and other green construction materials under the project titled “Promoting Sustainable Building in Bangladesh” funded by the European Union. The project will be implemented for promoting AB amongst consumer and producer groups for wider replication and commercialization across Bangladesh. The project aims to test a model that market incentives can lead toward sustainable consumption and production (SCP) practices through adoption of AB and other green construction materials within the construction sector.

Fig. 32 Some of the designed house forms for different climatic zones of Bangladesh, from the Design Catalogue. (a) House form for coastal areas, (b) house form for flood plain areas, (c) floating house form, (d) load bearing Earth bag house form, (e) stilt house form, and (f) house form for hilly areas. Data from Housing and Building Research Institute.

Application of Ferrocement Technology in Rural Housing

This project is running in collaboration with the Prime Minister's office. The aim of this initiative is to disseminate the ferrocement technology in the rural areas of Bangladesh.

Technical Development to Upgrade Structural Integrity of Buildings in Densely Populated Urban Areas and Its Strategic Implementation Toward Resilience Cities in Bangladesh (Tsuib), The Verification Survey of NonFired Brick

This project has just been initiated in collaboration between HBRI and Japan International Cooperation Agency (JICA).

Conclusion

With a target of achieving zero use of agricultural topsoil and saving agricultural land stock HBRI is working relentlessly. It has already achieved success regarding research on the alternative building material; moreover special emphasis is required for extension services of the institute to implement and disseminate newly developed agriculture and environment-friendly technologies and building materials. Application of ferrocement technology as an alternative to traditional RC construction, and multiple alternative blocks to conventional bricks, are some of the emerging alternative materials that comprise many of HBRI's research initiatives. The government's attempt toward the agricultural land protection and land use bill may have some prospects, but special emphasis needs to be given regarding unregulated conversion of agricultural land to nonagricultural uses, restrictions regarding construction of brick fields, and production of bricks. Hence, there is an emerging need to build a new set of construction trends that is agriculture and environment friendly.

Acknowledgments

We would like to convey our warm gratitude to these personnel for their contribution in many ways: Ar. Mohammad Fuad Abdul Quaium (GHORAMIJON), Ar. Shafinaz Sameen, Md. Masbha Uddin, Ar. Tamanna Mannan, Ar. Sadia Sharmin, Ar. Hamidul Haque, Md. Riazul Halim, and other concerned staff from HBRI.

Analysis of the Indian Traditional *Loha Shodhana* Process for Biocompatibility

BP Hari Chandra, Ramaiah Institute of Technology, Bengaluru, India

SV Prakash, Sri Krishna Institute of Technology, Bengaluru, Karnataka, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Indian metallurgical marvels have drawn the attention of scientists and technocrats across the globe. Some typical examples are: (1) The Delhi Iron Pillar which is a rustless pillar available in open air in Delhi, India and has excellent corrosion resistance since over 1700 years. (2) Damascus swords which are Wootz Steel swords with gold interlaced steel handles, are unable to be duplicated till date. (3) Bell metal canons and other metallic canons available and spread over several parts of India available till date. While there are these marvels on one side, on the other side there are several texts authored around the same time, which explain several material processing techniques including metals and non-metals like the rocks, gem stones etc. Gopalakrishnan (2009) lists out the names of 200 texts on *rasashastra*, the Indian materials science and material processing techniques and technologies, preparation of instruments and implements including surgical instruments used in traditional system of medicine.

A curiosity arose that in these texts, which are almost of the same time period as that of the metallurgical marvels, there could be directly or indirectly some information available related to material processing. Hence it was thought that investigating these literatures would be worth. One of these literatures is the '*Rasa Ratna Samucchaya*' (RRS) authored by Vagbhatacharya, is estimated to be written in dated in ninth century CE (Upadyaya, 2006; Dube, 1991). RRS has altogether 1230 *shlokas*/verses (Explanation/transfer of information/knowledge today is majorly in the prose form. Traditionally they were done in poetic form which was easy to learn by-heart and remember. One of such poetic forms of explanation are through what are traditionally called *shlokas*). (poetic explanations) (Satpute, 2006).

One of the *shlokas* on purification of metals aimed at detoxification looked to be quite interesting. Hence it was taken up for research. This *shloka* reads as follows:

taila takre gavāmūtre hyāranāle kulattaje

kramānnīśecayet taptam drāve drāve tu saptadā

svamādi loha patrāmām śuddhireṣā praśaśyate

The above *shloka* means: "Metals are made into thin leaves (sheets), heated intensively, and then quenched in *Taila* (Gingili oil (sesame oil)), *Takra* (Butter milk), *Gomutra* (Cow's urine), *Aaranala* (Rice gruel) and *Kulattha quatha* (Decoction of horse gram) in that order for seven times, in each of the liquids. This process suits the most to purify gold and other metals" (Satpute, 2006). This process is an initial phase of preparation of the nano-herbo-metallic complexes called the *bhasmas*. The other two phases are (1). Incineration, and (2). Special treatments based on the disease/disorder the *bhasma* is meant to cure. These *bhasmas* are used as ingredients in medicines to cure various diseases/disorders. These *bhasmas* are prepared of several metals like gold, silver, lead, tin, iron etc. If the *bhasmas* are prepared out of iron (*loha*), they are called *loha bhasma*. All these metals are detoxified by the same process as explained; although there are other alternate options in each case. However, after the above process called *samanya* (ordinary) *shodhana*, the metals undergo yet another stage of purification which is specific to the metal, called the *vishesha* (special) *shodhana*. In the current research iron is chosen. For *vishesha shodhana* of iron, the iron after the ordinary *shodhana* is subjected to seven more cycles of quenching with *triphalā* (Triphala=3 fruits: Indian gooseberry (Phyllanthus emblica), Chebulic myrobalans (Terminalia chebula), and Belleric myrobalans (Terminalia bellerica)) decoction as the quenchant. Thus in a complete *shodhana* process, the metal would undergo totally 42 steps of heat-quench cycles in six different quenchants as explained above. Fig. 1 shows a simplified flow chart of the process.

The modern work on the process only explain that the *shodhana* process is important in detoxifying the metal, and there are only limited studies from materials science point of view in the area. Further Nikalje (2015) who explain about the history of use of nano metallic medicine states that the first book on the same was authored by Freitas in 1999. However there are hundreds of traditional books available in India which explain about them which are centuries old. This indicates that modern researchers are not aware of the traditional literature, indicating poor availability of modern studies in the area; more so from materials science perspective. Hence this work was taken up. The aim of the current research was to determine the changes the metal undergoes during the *shodhana* process from materials science perspective.

Fig. 1 Flow diagram of *shodhana* process.

Materials and Methods

The process of *shodhana* which is currently studied is a process which is common for metals like gold, silver, iron, copper, lead, tin etc., out of which *bhasmas* are prepared (Satpute, 2006). The current research is limited to *shodhana* of *loha* (iron/steel). Further pure iron, low carbon steel, high carbon steels are used in preparation of *bhasmas*. Considering the reported literature (Rajendraprasad *et al.*, 2010) and observations made in industries, in the current research *loha* (high carbon steel) was selected. Turnings were obtained from the *loha* rods, and were used as the raw material for *shodhana*.

Quenchant preparation: Branded Gingili oil (*Taila*) was purchased. Butter milk (*Takra*), Cow's urine (*Gomutra*), Rice Starch (*Hyaranala*), Horse gram decoction (*Kulatha*), three fruits' decoction were prepared as per traditional norms.

Performing *shodhana*: The turnings were heated to a temperature of 750 C in a muffle furnace. Arbitrarily 15 min of soaking time was provided. The red hot turnings were removed from the furnace and poured into oils that was kept ready. Once the turnings reached room temperature, they were removed from the quenchant, heated again and quenched. After each quench a sample was taken for characterization. The process is repeated for seven times. This completes one stage of 6 stages. The sample obtained at the end of first stage is taken for the second stage. As in the first stage, the sample was heated to 750 C, soaked for 15 min and quenched in the second fluid, the butter milk. The process is repeated for seven times to complete the second stage of *shodhana*. On similar lines, all the remaining four stages of *shodhana* was completed by quenching in cow's urine, starch, horsegam decoction and the three fruits (*triphala*) decoction, and samples was taken after each quench for characterization. The samples were labelled and stored in desiccators till they were taken for characterization.

Characterization: Although at the end of *shodhana* there are 42 samples, characterization was done only for samples obtained at the end of each stage. Raw sample and a commercial *loha* bhasma samples were also characterized. Thus characterization was done for six samples, and the raw sample; they being named as S0 (raw sample), S7 (sample obtained after seven quenches (at the end of stage 1)), S14, S21, S28, S35 and S42 and *loha bhasma* (LB). Powder X-Ray Diffraction (PXRD) technique was used to determine the change in composition and structure, Fourier Transform Infrared Spectroscopy (FTIR) and Raman Spectroscopy were used to determine the chemical composition of the samples. Several other chemical tests were used based on the results of the tests, and are explained in the Results and Discussion section.

Results and Discussion

PXRD Results

Fig. 2 shows the PXRD patterns of the *loha* before *shodhana*, at the end of each stage of *shodhana* and that of *loha bhasma*. The following observations can be made from the PXRD patterns pertaining to *loha* and *loha bhasma*. The raw *loha* sample (S0) shows two peaks at $2\theta = 44.77^\circ$ (A) and 65.19° (B) which correspond to cubic Fe (JCPDS No. 01-087-0722). The peak at A is actually a split peak with peaks at 44.77° and 45.07° . The peak at 44.77° is the one which corresponds to Fe (JCPDS No. 01-087-0722). Since Fe is expected in the raw sample, the same is considered here. The diffractogram also shows peak at $2\theta = 72.702$ which corresponds to Fe_2O_3 (JCPDS No. 01-084-0308).

At the end of first stage of *shodhana* the sample (S7), the peaks at $2\theta = 45.07^\circ$ (A) and 65.19° (B) of the untreated *loha* (S0), which correspond to Fe have disappeared. However the peak at $2\theta = 72.702^\circ$ (C) which corresponds to Fe_2O_3 (JCPDS No. 01-084-0308) is retained as it is in various stages of *shodhana*. The peak also appears in *loha bhasma*. New peaks have appeared at various angles. The same is explained hereon. A peak appears at $2\theta = 33.6^\circ$ (D). However this peak exists only in S7 and does not appear neither in any of the other stages of *shodhana* nor in *loha bhasma*. This peak could not be attributed to any element/compound due to their non-availability in the available databases. The peak at $2\theta = 36.14^\circ$ (E) corresponds to $\text{Fe}_{0.925}\text{O}$ (JCPDS No. 01-089-0686). This peak exists only in S7 and does not appear back in any of the other stages of *shodhana*. The peak does not appear in *loha bhasma* also. The peak at $2\theta = 44.61^\circ$ (G) refers to Fe. (JCPDS No. 00-006-0696). This peak appears in all the diffractograms from S7 to S42 except in S21. The peak also appears in *loha bhasma*. The peak at $2\theta = 63.08^\circ$ (I) refers to Fe_3O_4 , appears in S7. It does not appear in any other stages of *shodhana*; but appears in *loha bhasma*.

S14 has a number of other new peaks. The peak at $2\theta = 33.13^\circ$ (K) to Fe_2O_3 (JCPDS No. 01-079-1741). This peak continues to exist in all the stages of *shodhana*, and in *loha bhasma*. The peaks at $2\theta = 41.09^\circ$ (M) and 49.66° (N) corresponds to Fe_2O_3 (JCPDS No. 01-084-0308). These peaks continue to exist in all the stages of *shodhana*, and in *loha bhasma*.

Fig. 2 PXRD patterns of *loha* before and after different stages of *shodhana*, and *loha bhasma*. (■ Fe, ■ Fe_2O_3 , ■ Fe_3O_4 , ■ $\text{Fe}_{0.925}\text{O}$).

The peaks at $2\theta = 35.66^\circ$ (L), 54.19° (P) and 75.60° (V) correspond to Fe_2O_3 (JCPDS No. 01-089-0599). These peaks continue to exist in all the stages of *shodhana*, and in *loha bhasma*. The peaks at $2\theta = 62.46^\circ$ (S) and 72.26° (U) correspond to Fe_2O_3 (JCPDS No. 00-033-0664). The peak at $2\theta = 64.19^\circ$ (T) corresponds to $\text{Fe}_{0.925}\text{O}$ (JCPDS No. 01-089-0689). The Fe_2O_3 peak at S continues to exist till all the stages of *shodhana*, but not in *loha bhasma*. The Fe_2O_3 peak at U exists only till S21. The two peaks that correspond to Fe_3O_4 are the ones at $2\theta = 56.93^\circ$ (Q) and 57.5° (R). The Fe_3O_4 peak at Q persists only till S21, but the one at R continues to appear in all the stages of *shodhana* as well as in the *loha bhasma*.

Two extra peaks start appearing at S21, they being the peaks at $2\theta = 69.65^\circ$ (X) and 77.95° (Z), both of which continues to exist till all the stages of *shodhana*, and in *loha bhasma* and correspond to Fe_2O_3 (JCPDS No. 01-079-1741).

Two new peaks start appearing from S28. The peak at $2\theta = 24.14^\circ$ (W) and 71.97° (Y). These peaks correspond to Fe_2O_3 (JCPDS nos. 00-033-0664 and 01-079-1741) respectively. There are no changes in the PXRD patterns of S35 and S42, and remain same as that of S28. However, in *loha bhasma*, there are new peaks at $2\theta = 30.30^\circ$ (γ), 43.36° (δ) and 74.51° (ϵ), all of which correspond to Fe_3O_4 (JCPDS No. 01-075-0449).

To summarize, PXRD results indicate that as the *shodhana* progresses, the Fe peaks deteriorate and disappear and a number of iron oxide peaks viz., Fe_2O_3 , Fe_3O_4 and $\text{Fe}_{0.925}\text{O}$ appear. Although Fe peak appeared, they are low intensity, non repetitive peaks. Of the iron oxide peaks, Fe_2O_3 peaks are prominent and have highest intensity. Formation of stable iron oxide (Fe_2O_3) is due to repeated heat-quench cycles as part of *shodhana*. *Loha bhasma* also showed highest intensity peaks for stable iron oxide (Fe_2O_3), with traces of unstable iron oxides (Fe_3O_4 and $\text{Fe}_{0.925}\text{O}$).

Results of FTIR of Shodhana

Fig. 3 shows the FTIR spectra of the *loha* before *shodhana*, at the end of each stage of *shodhana* and that of *loha bhasma*. The FTIR spectra shows peaks at wavenumbers of $470\text{--}475\text{ cm}^{-1}$ which indicates Fe_2O_3 peaks. The peak in this range has not appeared in S0

Fig. 3 FTIR spectra of *loha* before *shodhana*, at different stages of *shodhana*, and of *loha bhasma*. Note: The region covered by the legend had no peaks.

and S7; but has started with S14 onwards and persists in all the stages of *shodhana* (till S42). This suggests the formation of Fe_2O_3 due to oxidation of *loha* turnings.

The FTIR spectra of S0 shows low intensity peaks at 2920 and 2854 cm^{-1} which correspond to C–H alkane peaks (Xiong *et al.*, 2006) which remains as a weak peak as *shodhana* progresses. The peak could be because of the coolant used while turning. Rest, the spectra of S0 shows no other significant peaks. As the *shodhana* starts, S7 shows new peaks. The broad medium peak at 3435 cm^{-1} indicates water peaks which are due to adsorbed moisture. This peak exists in all the stages of *shodhana* and also in the *loha bhasma*. The peak at 1631 cm^{-1} corresponds to C–O bending peaks (Shokri *et al.*, 2009). This medium intensity peak exists in all the stages of *shodhana* and also in *loha bhasma*.

Another peak at 1572 cm^{-1} corresponds to carboxylate group (RCOO^-) (Sathyanarayana, 2015). This low intensity peak appears in all the stages of *shodhana* but does not appear in *loha bhasma*. The peak at 1745 cm^{-1} refers to carboxylic acid groups (Vander, 2002). The peak appears in S14, S28 and S35. The peaks at 1415 cm^{-1} refers to carboxylic acid moieties (Vander, 2002). This peak appears in all the stages of *shodhana* and in *loha bhasma*. The peak at 1384 cm^{-1} refers to carbonyl peak (Xiong *et al.*, 2006) which appears in all the stages of *shodhana* except S14. The peak does not appear in *loha bhasma*.

Another peak between 1104 and 1113 cm^{-1} appears in all the stages of *shodhana* as small peaks and in *loha bhasma* as a high peak. These peaks correspond to Si–O–Si stretching vibration mode (Senthil Kumar and Rajkumar, 2014). The peak at 1046 cm^{-1} appears in S7, S14 and S35. This peak corresponds to C–O–C symmetric stretching and is due to the presence of a ligand called sesamol, a component of gingili (sesame) oil (Mirghani *et al.*, 2003). The peak does not appear in *loha bhasma*.

Iron oxide (FeO) peaks at $\sim 570\text{ cm}^{-1}$ appears in S7 and S14 only. The peak does not appear later on, neither in *loha bhasma*. New peaks appear with S21 at 550 – 557 cm^{-1} . The peak continues to exist in all the stages of *shodhana* and in *loha bhasma*. The peak indicate vibrations corresponding to Fe_2O_3 (Zhang *et al.*, 2013). Fe_2O_3 peak start appearing with S14 and continues till the last stage of *shodhana*. This Fe_2O_3 peak is between 470 and 475 cm^{-1} (Woo *et al.*, 2003). There are several other new peaks that appear in *loha bhasma* alone which are all low intensity peaks, which could be attributed to later stages of *bhasma* preparation, viz., the *maarana* and *vishesha sanskarana*.

Overall, the presence of various organic bonds along with Fe–O bonds can be attributed to the interaction of the quenchant with the hot metal. These results are similar to the one obtained in *shodhana* of mild steel.

To summarize, through FTIR analysis of samples of *shodhana* it can be observed that Fe–O bonds of Fe_2O_3 are indicated. There are indications of presence of unstable FeO in the initial stages of *shodhana*. Apart from these metal oxide bonds, there are a number of organic bonds involving C–H bonds due to carboxylic acid groups, alkane peaks, aromatic groups whose presence is attributed to the organic quenchant since all organic compounds invariably have C–H bonds. In addition to these C–H bonds there are water peaks and C–O peaks due to adsorbed moisture and carbon-di-oxide. Si–O–Si bonds are indicated due to presence of Si in the *lohas*, which gets oxidized during quenching. *Loha bhasma* also indicated similar results. Overall, the results of FTIR with respect to formation of majorly Fe_2O_3 is in consistence with the results of PXRD.

Results of Raman Spectroscopy

Fig. 4 shows the Raman spectra of the *loha* before *shodhana*, at the end of each stage of *shodhana* and that of *loha bhasma*. The Raman spectrum of S0 shows no significant peaks. This is because of the fact that metals do not show peaks in a Raman spectrum. The Raman spectrum of S7 shows low intensity peaks at wavenumbers of 294 and 412 cm^{-1} . Both these peaks correspond to iron-oxygen bond vibrations of Fe_2O_3 (RRUFF No. R050300). The Raman spectrum of S14 shows only one low intensity peak at wavenumber of 294 cm^{-1} . This peak corresponds to iron-oxygen bond vibrations of Fe_2O_3 (RRUFF No. R050300). The Raman spectrum of S21 shows a high intensity peak at wavenumber of 226 cm^{-1} which corresponds to Fe_2O_3 (RRUFF No. R040025). The peaks at 244 , 246 , 292 , and 409 cm^{-1} corresponds to Fe_2O_3 (RRUFF No. R050300). The peaks at 494 and 609 cm^{-1} also correspond to Fe_2O_3 (Shim and Duffy, 2002). One low peak at 651 cm^{-1} corresponds to Fe_3O_4 (RRUFF No. R060222). The Raman spectrum of S28 shows a high intensity peak at wavenumber of 226 cm^{-1} which corresponds to Fe_2O_3 (RRUFF No. R040025). The peaks at 293 , 409 and 611 cm^{-1} also correspond to Fe_2O_3 (RRUFF No. R060191). Thus all the peaks in S28 correspond to Fe_2O_3 . The Raman spectrum of S35 shows a high intensity peak at wavenumber of 226 cm^{-1} which corresponds to Fe_2O_3 (RRUFF No. R040025). The peaks at 244 , 293 , 409 and 611 cm^{-1} correspond to Fe_2O_3 (RRUFF No. R050300). The peak at 494 cm^{-1} also corresponds to Fe_2O_3 (Shim and Duffy, 2002). A low intensity peak appears at 657 cm^{-1} which corresponds to Fe_3O_4 (RRUFF No. R060222). Peaks at 485 and 506 cm^{-1} could not be identified from the available database. Finally, in the Raman spectrum of last stage of *shodhana*, S42 shows a high intensity peak at wavenumber of 223 cm^{-1} which corresponds to Fe_2O_3 (RRUFF No. R040025). The peaks at 292 , 409 and 611 cm^{-1} corresponds to Fe_2O_3 (RRUFF No. R050300). The peak at 496 cm^{-1} also corresponds to Fe_2O_3 (Shim and Duffy, 2002). The peak at 488 cm^{-1} could not be identified from the available database. Raman database was checked for presence of Fe_3O_4 and it was found that there is no presence of Fe_3O_4 peaks other than those mentioned above.

Thus, the Raman spectra taken after different stages of *shodhana* of EN shows majorly peaks corresponding to the iron-oxygen bond vibrations of Fe_2O_3 . Low intensity peaks corresponding to the Fe_3O_4 bonds appear in S21 and S35. They are also indicated in the PXRD results. However PXRD results also show single peaks corresponding to Fe_3O_4 in all the stages of *shodhana* of EN except S7.

To summarize, Raman spectra indicate the presence of peaks corresponding to majorly the stable Fe_2O_3 in all stages of *shodhana* and in *loha bhasma*. Although there are peaks corresponding to other iron oxides, they are low intensity peaks. Further, though

Fig. 4 Raman spectra of *shodhana* of loha, and *loha bhasma*.

there are other unidentified peaks, it was confirmed through the available RRUFF and other database that they are not corresponding to Fe_3O_4 . Several other peaks could not be identified which could be organic peaks. The results of Raman spectroscopy is in consistency with the results of PXRD and FTIR with respect to formation of majorly Fe_2O_3 .

Chemical Based Tests

From the PXRD, FTIR and Raman Spectroscopy tests it was noted that after *shodhana* the material has turned into a very stable Fe_2O_3 with a number of metallo-organic complexes. Minor peaks of Fe_3O_4 was also detected. Earlier reports, which was also a material science based work, indicate that *shodhana* renders the material into an easily digestible form (Krishnamachary *et al.*, 2012). Since the result was in contrary to the already published results, more tests were conducted to validate the current result. In order to validate the same several chemical based tests were conducted. The sample obtained at the end of *shodhana* was tested to be digested in strong acid and strong base. The sample was neither digestible in strong acid (pH ~ 1), nor strong base (pH = 10), even upon boiling in them.

Since the sample after *shodhana* could not be digested even after boiling in the strong acid/base it can inferred that it has turned into a form which cannot be digested by the human system,. Thus, this result is in contrary with an earlier published research. The difference in the result could be because earlier researchers had quenched the raw material for only 3 times in each quenchant, thus finishing the *shodhana* process in $3 \times 6 = 18$ steps, unlike in the current study it was $7 \times 6 = 42$ steps. Further, the heating temperature chosen by the earlier researcher was 530–560°C, and in the current research is 750°C. Even in the current research, during the pilot study a temperature of 530–560°C was chosen. However, by the time the material was removed from the muffle furnace and dropped into the quenchant, the temperature of the *loha* turned low indicated by the blackish color of the *loha* as it got into the quenchant. Further, the temperature chosen here was 750°C since earlier researchers, who have prepared *loha bhasma* for clinical research have reported a preparation temperature of 750–850°C (Rajendraprasad *et al.*, 2010; Rao and Naidu, 2011; Gupta and J, 2012). Also, in the current research it was noted that while conducting *shodhana* of low melting point metals like lead/tin the metal was liquefied and poured into the quenchants (Rajput *et al.*, 2013; Sarkar *et al.*, 2010). Considering this, a higher temperature was preferred, and thus chosen 750°C.

Thus from the current research it can be concluded that the *loha* after *shodhana* has turned the material to an indigestible form, and after completing the later stages of *bhasma* preparation, the resulting nano-herbo-metallic complex, the *loha bhasma* produced also is indigestible, which was also confirmed experimentally in the current research by testing commercially available *loha bhasma*. Another point that could be noted is that there were be traces of Fe_3O_4 which could provide easily assimilable Fe^{2+} ions upon reaction with digestive juices. Thus, with the current research, from materials science point of view, it can be hypothesized that human body cannot digest the major part of *loha bhasma*, and might only act as a messenger in the body, which needs to be confirmed by clinical studies by appropriate researchers. This property of the *loha bhasma* is attributed to the *loha shodhana* process.

Finally, what is biocompatibility? Whether the *loha bhasma* should be digestible or not digestible? Whether it is aimed at acting as a messenger by being inert or should it provide digestible form of iron ions upon its consumption? These are the question to be answered by the appropriate medical science community to decide on the process parameters for preparation of *loha bhasmas*; since the property of the end product significantly depends on the process parameters, and standard operating procedures for preparation of *loha bhasma* should be decided on by both material and medical scientists working together.

Conclusion

Loha shodhana renders *loha* (iron) into stable Fe_2O_3 , a form which is capped with organic bonds, which from materials science point of view is indigestible by the neither strong acid not base, and hence by the human digestive system also. The *loha bhasma* which is the end product after processing the *loha* after its *shodhana* is also indigestible the property of which is attributed to the *shodhana* process. The current research provides a hypothesis to the clinical researchers that *loha bhasmas* are indigestible form and might act as a messenger in the human body. Further, there needs standardization in the operating procedures for preparation of *loha bhasmas*, since there are significant differences in the property of the *loha* as the parameters vary.

Analyzing Biodiesel Production From Cooking Oil

Dalibor Petković, University of Niš, Pedagogical Faculty in Vranje, Partizanska, Vranje, Serbia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Biodiesel derived from waste cooking oil is considered highly environmentally sustainable since waste cooking oil is a waste product from domestic and commercial cooking processes and then recycled to a transportation fuel in Singapore. In addition, it avoids the conversion of land use for crop production.

The collectors and recyclers should convince the food establishments and suppliers of cooking oil of the benefits of recycling cooking oil, which in turn obtains a steady source of waste cooking oil as feedstock for biodiesel production. As the biodiesel life cycle defined is very much dependent on waste cooking oil as a feedstock, it is recommended to optimize the waste cooking oil collection route based on location of the suppliers.

In this article the collection of waste cooking oil is investigated based on the location of suppliers, such as a pilot-scaled collection and production scheme in large estates. For such purpose a waste cooking oil software is modelled which will help in the collection of waste cooking oil by optimizing the optimal route of the waste cooking oil based on the suppliers' locations.

Waste cooking oil management process could be very complex task because of many different suppliers and collectors. There is need to make optimal route for the most efficient transport of the waste cooking oil from users to the collectors. The main problem is suppliers motivation for such a process since they require simple and understandable process for the waste cooking oil management. Because of that it is suitable for the waste cooking oil transport to model an software which will make more motivation for suppliers and collectors to make stronger and more uniform connections. The software could determine the optimal routes for the waste cooking oil based on locations of suppliers. In this article object orientated approach is used for the software modeling (Lethbridge and Laganier, 2005; Jacobson, 1993).

Object-orientated modeling strategy is an attempt to encapsulate data and process into thing called objects. The data in the objects could be created, deleted or used only by some encapsulated processes or methods. Unified modeling language (UML) is a standard tool for object orientated modeling which could help to developers and engineers to make detailed specification and documentation of any system.

UML (Rumbaugh *et al.*, 2004) is a graphical language which is effective for visualization, specification, construction and documentation of a system's artifact which is software intensive. UML has standard practices for writing a blueprint of system. By using UML one can cover various conceptual things such as functionality by use cases and business processes.

Modeling and analyzing of various activities in any system by UML can help to visualize, specify, constructs and document the system artifact effectively which is helpful for better understanding of the problem and for various stakeholders of the application of the waste cooking oil.

Literature Overview

In paper (da Silva César *et al.*, 2017) authors examined the opportunity for biodiesel production from WCO as a potential source for future energy supply, particularly for biodiesel, and in this case, they analyzed the Brazilian scene. Several related aspects are covered, such as the physical and chemical properties of the WCO and the biodiesel made from it (da Silva César *et al.*, 2017). The waste cooking oil was used as a raw material for biodiesel production and their different fatty acids were determined by gas chromatography coupled with flame ionization detector (GC-FID) in article (Ullah *et al.*, 2017) where kinetic study of this transesterification reaction was evaluated and followed the first-order reaction mechanism. Paper (de Araújo *et al.*, 2013) aimed at the assessment of the methods of production of biodiesel from different types of used cooking oil. Researches into the productive chain of this type of biofuel were performed in Brazil while several scientific studies approaching processes of pretreatment and transesterification of waste cooking oil were analyzed with their possible variations: alkaline catalysis, acid catalysis, enzymatic catalysis and non-catalytic conversion techniques, highlighting the main advantages and disadvantages of each analyzed route. Transesterification reaction parameters to produce the lowest kinematic viscosity waste cooking oil biodiesel by using sodium hydroxide (NaOH) as catalyst and ethanol (C₂H₅OH) as alcohol was determined in article (Bilgin *et al.*, 2015) and according to results, reaction parameters giving the lowest kinematic viscosity of 4.387 cSt were determined as 1.25% catalyst concentration, 70°C reaction temperature, 120 min reaction time and 12:1 alcohol/oil molar ratio. Development of cleaner biodiesel production related to hydrodynamic cavitation of methyl ester synthesis from sustainable waste cooking oil via alkali-catalysed transesterification is gaining importance due to considerable lower energy requirement and time. The effects of the oil to methanol molar ratio (1:4–1:7), catalyst concentration (0.5–1.25 wt%) and reaction temperature (50–65°C) have been studied in a hydrodynamic cavitation and mechanical stirring system (Chuah *et al.*, 2017). In conclusion, waste cooking oil methyl ester produced via hydrodynamic cavitation proved to be time saving and energy efficient compared to mechanical stirring. This makes the process more environmental friendly

using hydrodynamic cavitation (Chuah *et al.*, 2017). The comprehensive spray and combustion characteristics of waste cooking oil (WCO) biodiesel (B100) and conventional diesel fuels were investigated in article (Hwang *et al.*, 2016) where the combustion imaging showed that the WCO biodiesel had lower flame luminosity and shorter visible flame duration than diesel. Study (Hong *et al.*, 2016) was carried out for manufacturing biodiesel from WCO using microwave assisted-transesterification reaction, and the efficiency of the original and new methods was compared. The biodiesel fuel properties such as fatty acid methyl ester (FAME) content, higher heating value (HHV), and kinematic viscosity (KV) of six acid value WCO based biodiesel were analyzed where it was found that as the acid value increased, more catalyst amount, microwave power, reaction time, and molar ratio of alcohol/WCO were needed. Therefore, biodiesel using commercial WCO can be produced without pretreatment process (Hong *et al.*, 2016). Used waste cooking oil (WCO) or frying oils are being considered as rich sources of economical feedstock for biodiesel production. To carry out the process of trans-esterification of WCO to methyl esters (biodiesel), zeolite/chitosan/KOH composite was used as solid heterogeneous catalysts. The conversion of biodiesel from WCO was obtained for 1 wt% catalyst concentration and alcohol/oil ratio of 1:7 at 40 V in the presence of water as 2 wt % of the whole solution in 3 h, produced 93% yield (Fereidooni and Mehrpooya, 2017). The catalytic esterification of waste cooking oil (WCO) with methanol could be easily achieved by using C-SO₃H and therefore the sulfonated carbon-based solid acid catalyst was thus designed to be an active, stable and reusable solid acid as an environmentally benign replacement for homogeneous catalyst (Wei *et al.*, 2017). The application of an environmentally benign sulfonated carbon microsphere catalyst for biodiesel production from waste cooking oil was investigated in article (Tran *et al.*, 2016) where the highest biodiesel yield (89.6%) was obtained at a reaction temperature of 110°C, duration time of 4 h, and catalyst loading of 10 wt % under elevated pressure 2.3 bar and 1.4 bar for first and second step, respectively. The reusability of the catalyst was investigated and showed that the biodiesel yield decreased by 9% with each cycle; however, this catalyst is still of interest because it is an example of green chemistry, is nontoxic, and makes use of xylose waste (Tran *et al.*, 2016). In study (Babaki *et al.*, 2017) was developed a multi-enzyme system to produce biodiesel with waste cooking oil and methanol where verification experiment confirmed the validity of the predicted model. Paper (Xiang *et al.*, 2017) studied the effects of using modified coal fly ash as a catalyst to convert waste cooking oil (WCO) into biodiesel under microwave-strengthened action where the experimental results showed that the modified coal fly ash catalyst improved biodiesel yields under the microwave-assisted system, and the maximum biodiesel yield from waste cooking oil reached 94.91% at a molar ratio of methanol to WCO of 9.67:1 with 3.99 wt% of modified coal fly ash catalyst (based on oil weight) at a 66.20°C reaction temperature. In work (Joshi *et al.*, 2017), high speed homogenizer has been used for the intensification of biodiesel synthesis from soybean oil and waste cooking oil (WCO) used as a sustainable feedstock. High acid value waste cooking oil (27 mg of KOH/g of oil) was first esterified with methanol using sulphuric acid as catalyst in two stages to bring the acid value to desired value of 1.5 mg of KOH/g of oil. Transesterification of soybean oil (directly due to lower acid value) and esterified waste cooking oil was performed in the presence of heterogeneous catalyst (CaO) for the production of biodiesel. Overall it can be concluded from this study that high speed homogenizer can be used as an alternate cavitating device to efficiently produce biodiesel in the presence of heterogeneous catalysts (Joshi *et al.*, 2017). The objective of the work (Qu *et al.*, 2016) was to investigate the influence of waste cooking oil biodiesel on oxidation reactivity and nanostructure of particulate matter (PM) where the test was carried out in a small agricultural diesel engine. Study (Jung *et al.*, 2017) laid an emphasis on the possible employment of biochar generated from pyrolysis of chicken manure to establish a green platform for producing biodiesel where to this end, the pseudo-catalytic transesterification reaction using chicken manure biochar and waste cooking oil was investigated. In study (Ali *et al.*, 2017), waste cooking oil (WCO) was evaluated as feedstock for biodiesel production using free lipase in liquid where the response surface methodology (RSM) was used to optimize the interaction between four factors: The reaction temperature, methanol-oil molar ratio, dosage of lipase as biocatalyst and rotational speed. Due to their excellent physicochemical properties, biodiesel and n-pentanol are regarded as two promising alternative biofuels for automobile. However, the fundamental data of spray and combustion characteristics of n-pentanol/biodiesel blends are still scarce. The objective of work (Ma *et al.*, 2017) was to investigate the effects of n-pentanol addition to waste cooking oil (WCO) biodiesel in different ratios (0%, 20%, and 40% in vol) on spray, ignition and combustion characteristics in a constant volume combustion bomb (CVCB) where result also suggested that, for multi-component fuels, flame lift-off length (FL) is the most reliable factor that influence the soot concentration level under spray combustion processes, rather than ignition delay or soot formation time. Study (Wei *et al.*, 2017) investigated the influence of waste cooking oil (WCO) biodiesel on the combustion, unregulated gaseous emissions and particulate emissions of a diesel engine. Experiments were carried out on a direct-injection diesel engine fueled with diesel, B20 (20% biodiesel on volume basis), B50, B75 and biodiesel, under the Japanese 13-mode test cycle where overall, the influence of biodiesel on the investigated emissions is proportional to the biodiesel content in the tested fuels (Wei *et al.*, 2017).

Methodologies for Software Development

Generally, the software development methodology consisted of procedures, techniques, tools and documentation which helps in the software development process. Software development methodology describes all steps and phases of the software development. The methodology suggests tools and techniques which should be used in the particular step of the software development. Also the methodology could suggest how to plan and track process of the software development and testing as well.

Many companies use the methodologies for software development in order to ensure the consistency of the problem solution, to decrease the possible errors, to acquire the full documentation for current and future projects and to get good final product which could be changeable and adaptable easily since the all steps and phases would be documented in detail and any new changes in the software models could be achieved before software coding.

Models could be describes as simplified presentation of reality. The models could be presented with some standard modeling language. The model presentation could be textual or graphical by diagrams. Each software could be described based on different aspects by structural models in order to show software structure with the main parts and their interconnections and relationships. Also there is behaviour models where one can track the software dynamics.

RUP Methodology

Rational Unified Process (RUP) is an interactive methodology for the software development based on architecture and use cases. RUP methodology is based on Unified Modeling Language (UML). UML is used for specification, visualization, construction and documentation of the software development.

RUP methodology has control of key or critical points through the development. In other words each phase of the RUP methodology should end with some control key or critical points where the achieved results are summed and future directions are planned based on the results. RUP methodology has artefacts (documents), models of model elements. Project requests are noted in the documents. Models are used to simplify the software architecture without unnecessary details. Model elements could help to visualize, construct and document the main structure and software behaviour. Fig. 1 shows the main elements of the RUP methodology. Each phase of the RUP methodology has iteration where disciplines are considered. The disciplines are described by process flow in details. The process shows activity and roles of everyone in the project. Finally, there are artefacts where one can see software documentation, software models and model elements.

RUP methodology has four main phases. The first phase is the initial phase or idea inception where one needs to understand what should be done and then the software vision and requirements are identified. This phase includes the identification of key software actors (users) and use cases. Also there is need to identify software domain. Use of case defines one sequence of an action which software performs that yields to an observable results. On the other hand one use case presents result of an action by actor (Fig. 2). Use case presents the main part of some complete software operation from beginning until to the end. It is used to capture the intended behaviour of the system in development. By use case models desired behaviour of the system could be specified but it is not strictly this desired behaviour to be carried out or implemented in the final product. Use case models can be developed for whole system or for the part of the system. Each part of the system or subsystem can be developed by use case models until the part produces some tangible amount of work and results. System complexity indicates the number of use cases. In the initial stage of system development main use cases are developed and additional use cases can be added or included when there is need for them.

The second phase is project elaboration where one needs to understand how to build the software and basic software architecture is showed in the phase. The third phase presents software construction where software testing is considered. The fourth phase presents software transition where software validation is performed. The RUP phases are shown in Fig. 3.

RUP models describe software in modeling. RUP models could be business models which describes business processes and business environment, use case models which describes what the software is doing and the software environment, projecting models which describe use case realization as code abstraction and implementation models which present collection of components and subsystems.

Software development process could have different problems which needs to be identified and solved before coding and testing. In order to solve problems there is need to find the problem causes. To remove the problem causes it is essential to use best

Fig. 1 Elements of RUP methodology.

Fig. 2 Use case model.

Fig. 3 RUP methodology phases.

practices. For example in order to remove the confusion in communication between team members it is suitable to use standard language UML for the software visualization, specification and documentation. There are different types of UML diagrams which can be used in the software development process. There are two main classes of the UML diagrams. These are structural and behavioral diagrams. Structural diagram presents structure of the system in passive state and behavioral diagram present the active behaviour of the objects in a system or dynamical state.

Object-Orientated Modeling of Business Process

UML is used for object-oriented modeling of business process. As already mentioned there are different UML diagrams for describing of software architecture and software behaviour. UML as standard language is used for modeling, for analyzing, for projecting and for implementation of the software system. Based on the object-oriented modeling all processes could be presented by use case models as rough specification and by structural diagrams and behavioral diagrams as detail specification.

During modeling of the business process it is not recommended to use natural language because of its ambiguity. Also, formal programming languages are not understandable for many people in the project team. Therefore it is suitable to organize the natural language to avoid ambiguity. Modeling process is one of the solutions for understanding and clear communication between project team members.

Modeling of the Optimal Route for Waste Cooking Oil

Problem Description

The problem is intended for solving of collection of waste cooking oil which is carcinogenic material. The main target of the model are the suppliers which are implemented in the software of the estimation of optimal route of waste cooking oil. The suppliers in this study are market objects, tourist industry, catering industry and industry objects.

The main goals of the investigation is to decrease the emissions of the greenhouse gases and generally to decrease global warming. Also biofuels need to be introduced in the transport as much as it can. The main activity of the investigation should be to develop the GPS system for mapping of the waste cooking oil suppliers in order to optimize the waste cooking oil transport.

Object-oriented modeling concepts are used during analyzing and modeling of the process of the optimization of route of waste cooking oil. Two UML concepts are used for the software modeling like use case models, activity diagrams, state diagrams and scenarios of activities.

Software for Route Optimization for Waste Cooking Oil Transport

Software for route optimization for waste cooking oil transport should be used for organization of the waste cooking oil suppliers and collectors as well. The main advantage of the software for route optimization for waste cooking oil transport in the article is in its universality and in its online usage.

The main feature of the software for route optimization for waste cooking oil transport should be universal application for any subjects and any suppliers and collectors. The software for route optimization for waste cooking oil transport will be framework of the suppliers and collectors of the transport activity.

As users are considered suppliers in different parts of industry and collectors as well, all of the users should have username and password in order to access the waste cooking oil management database.

Collectors should make reports for different statistical analysis of the waste cooking oil. As the main problem of the current software for route optimization for waste cooking oil transport it was identified limitation of unified approach for all subjects. Therefore, it is required to develop information system which would allow to users to use the software anytime in order to enter desired data.

Software users

The software users could be divided based on natural basis according to working place, suppliers and collectors. All of the users have equal rights to access and use of the software. Therefore the main users of the software are:

- Suppliers (market objects, touristy industry, catering industry and industry objects).
- Collectors.
- Administrator.

Each of the users should have individual username and password in order to access to the software. Administrator of information system who needs to maintain the software and he is responsible for working of computer system and software as well. He gives permission to the staff's access to the waste cooking oil management database, maintains database, maintains web presentation of the waste cooking oil management and makes regular daily reports.

Software Analyzing

Each of the users should have individual username and password in order to access to the software. Administrator of information system who needs to maintain the software is responsible for working of computer system and software as well. He gives

Fig. 4 Main use case diagram of the software for route optimization for waste cooking oil transport.

Fig. 5 Use case diagram – Software administration.

permission to the staff's access to the waste cooking oil management database, maintains database, maintains web presentation of the waste cooking oil management and makes regular daily reports.

During the analyzing process it is concluded that the suppliers and collectors of the waste cooking oil have the have universal software to improve the efficiency of the waste cooking oil acquiring. This software needs to have online and offline working regime since there is no need to be always online to track desired materials. The software should enable fast searching procedure for the material.

Main use cases diagram of the software

Transport process of the waste cooking oil are depicted by the main use case diagram as it shown in Fig. 4. The main use case diagram has several sub use cases which will be explained in detail. As can be seen, the administrator should perform the main administration process of the transport process in order to ensure smooth working processes by the software. Waste cooking oil transport clients or

Table 1 Specification of use case: Giving permission for database access

Title	<i>Giving permission for database access</i>
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the giving permission for database access
Pre-condition	PC is properly settled. Administrator has needed knowledge for the tasks
Post-condition	Client received authorization for database access of software
Main scenario	1. Administrator receives the request for the giving permission for database access of software 2. Administrator checks the request validity 3. Administrator fills the application form for the giving permission for database access of software 4. Administrator selects client category based on the quantity of the waste cooking oil 5. Administrator approves the request 6. Administrator prints the instruction for the application use 7. Administrator distributes the instruction to the client as the proof for the successful addition to the users of the waste cooking oil management software for the database access
Alternative	1. In the case if the request is incorrect filled based on the step 2. of the main scenario the administrator returns the request to the client with the instruction how to correct the errors in the request

Table 2 Specification of use case: Software maintaining

Title	<i>Software maintaining</i>
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the software maintaining
Pre-condition	PC is properly settled. Administrator has needed knowledge for the tasks
Post-condition	Backup of the waste cooking oil management software was made
Main scenario	1. Administrator checks if there is some large operation on the software 2. If there is some operation on the software, the administrator waits until the operation ends 3. If there is not operation on the software, the administrator prepares tools for the software maintaining 4. Administrator checks if the all functions of the software are proper 5. If some of the function of the software is not proper than the administrator starts the tool for correction of the function 6. Administrator starts the backup process of the software 7. Administrator records the time of the software backup
Alternative	None

Table 3 Specification of use case: Software web pages maintaining

Title	<i>Software web pages maintaining</i>
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the web pages maintaining of software
Pre-condition	PC is properly settled. Administrator has needed knowledge for the tasks
Post-condition	Backup of the web pages of software was made
Main scenario	1. Administrator checks if there is some large operation on the web pages of software 2. If there is some operation on the web pages of software, the administrator waits until the operation ends 3. If there is not operation on the web pages of software, the administrator prepares tools for the web pages of waste cooking oil management software maintaining 4. Administrator checks if the all functions of the web pages of software are proper 5. If some of the function of the web pages of education software is not proper than the administrator starts the tool for correction of the function 6. Administrator starts the backup process of the web pages of software 7. Administrator records the time of the web pages of software backup
Alternative	None

suppliers could record the quantity of the waste cooking oil if they are logged in the software database. Based on the GPS information of the suppliers the software should perform the calculation of the optimal route of the waste coking oil to the collectors.

Use cases of the software subsystems

Software administration

Based on the analyzing of waste cooking oil transport process it is noted that there is need for new computer system for the sector. Accordingly there is need for a person who will maintain administration of the software and the computer system. Therefore there is need for a software administrator.

Table 4 Specification of use case: Software database maintaining

Title	<i>Software database maintaining</i>
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the database maintaining of software
Pre-condition	PC is properly settled. Administrator has needed knowledge for the tasks
Post-condition	Backup of the database of software was made
Main scenario	1. Administrator checks if there is some large operation on the database of software 2. If there is some operation on the database of software, the administrator waits until the operation ends 3. If there is not operation on the database of software, the administrator prepares tools for the database of software maintaining 4. Administrator checks if the all functions of the database of software are proper 5. If some of the function of the database of software is not proper than the administrator starts the tool for correction of the function 6. Administrator starts the backup process of the database of software 7. Administrator records the time of the database of software backup
Alternative	None

Table 5 Specification of use case: Making of regular reports

Title	<i>Making of regular reports</i>
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the making of regular reports
Pre-condition	PC is properly settled. Administrator has needed knowledge for the tasks
Post-condition	The reposts were printed
Main scenario	1. Administrator checks if there is some large operation 2. If there is some operation, the administrator waits until the operation ends 3. If there is not operation, the administrator prepares tools for the making of regular reports 4. Administrator selects between standard procedure of the making of regular reports and nonstandard procedure where administrator can adjust the parameters of the reports. If nonstandard procedure was chosen than the administrator adjusts the parameters of the reports 5. Administrator starts the procedure of the making of regular reports 6. Administrator saves the backup of the reports 7. Administrator records the time of the database of making of regular reports
Alternative	None

Table 6 Specification of use case: Recording of quantity of waste cooking oil

Title	<i>Recording of quantity of waste cooking oil</i>
Actors	Suppliers
Trigger	It starts with the choosing of the option on user interface for the recording of quantity of waste cooking oil
Pre-condition	PC is properly settled. Waste cooking oil acquired
Post-condition	Recorded quantity of waste cooking oil
Main scenario	1. Client starts waste cooking oil management software 2. Client does login into waste cooking oil management education software 3. Client records the quantity of waste cooking oil 4. Client confirms the quantity
Alternative	1. The recording of quantity of waste cooking oil is canceled 2. Due to technical problems the service cannot be made

Administrator performs software administration in order to eliminate all unpredictable errors in the software and system. Administrator has full responsibility for the software maintenance. They will give permissions for other users access to the system, maintains the software, maintains the web pages of the software, maintains the software database, and makes regular daily reports. Fig. 5 shows the use case diagram of the software administration. As can be seen there are five functions of the administration which will be explained in details by scenarios.

Table 1 shows detailed specification of use case for giving permission for database access of the software by administrator.

Conclusion

Fossil fuels' pollution and their non-renewability have motivated the search for alternative fuels. Some common examples of seed oils are sunflower oil, date seed oil, soy bean oil. For instance, soy methyl and soy-based biodiesel are the main biodiesel. Biodiesel is a clean diesel fuel that can be produced through transesterification reaction. Recycled cooking oil, on the other hand, is one of the inexpensive, easily available sources for producing biodiesel.

The main innovation of the investigation is analyzing and modeling of new software for acquiring of waste cooking oil. The main suppliers could enter quantity of cooking oil in the software. Based on the quantity the collectors could decide which reconditioning process is suitable for the waste cooking oil. The main output should be produced biodiesel for transport.

Also software could map the GPS locations of the suppliers of the waste cooking oil in order to optimize the route of the waste cooking oil transport in order to decrease the transport time.

Introduction

Plastic recycling is an established process of recovering plastic scraps and waste into useful products. Based upon the waste management concept, plastic recycling can be broadly divided into four classifications namely: primary, secondary, tertiary and quaternary recycling (See Fig. 1). Primary and secondary recycling (recycling of clean, uncontaminated and single type waste: extrusion, moulding, heat treatment) are actually the mechanical recycling, tertiary recycling is performed by chemical means (dividing plastic waste into smaller molecules) and quaternary recycling is disposal by thermal utilization specially by energy recovery (Papargyropoulou *et al.*, 2014).

The primary recycling is an uncontaminated process in which only molecular arrangement/behavior are modified to apply the material in different processes (Kaminsky *et al.*, 1976; Singh *et al.*, 2017a). The secondary recycling is a mechanical mean of recycling process where polymers like, polyvinyl styrene (PVS), low density polyethylene (LDPE), high density polyethylene (HDPE), acrylonitrile butadiene styrene (ABS), polypropylene (PP), polyethylene terephthalate (PET), poly vinyl chloride (PVC), poly lactic acid (PLA) polystyrene (PS), polycarbonate (PC), polyamides (PA) and etc. are largely modified for preparation of feedstock or useful products (Seike *et al.*, 2018; Soo *et al.*, 2017; Wan *et al.*, 2017; Singh and Kumar, 2017b; Singh *et al.*, 2017c,d). The tertiary recycling process involves various methods of recycling including cracking, gasification, thermolysis and chemolysis (Hahladakis *et al.*, 2017; Horvat and Ng, 1999; López *et al.*, 2013). 'Incineration' is the quaternary recycling technique which is performed under the controlled combustion of the waste polymer. A small amount of the residue is the byproduct of this process which is further landfill or treated for environmental exposure (Gurgul *et al.*, 2018; Hwang *et al.*, 2017).

Differential scanning calorimetry (DSC) is an experimental thermo-analytical practice for investigating the difference in the amount of heat required to increase the temperature of a sample and reference is measured as a function of temperature. The glass transition temperature, degree of crystallinity, degree of polymerization, melting points, and solidification points are some of important physiognomies of metals, alloys, thermoplastics and composites which are generally measured by the concept of DSC analysis Kumar *et al.*, 2017a,b,c, 2018a,b. Thermal analysis is liable to examine the thermal properties of any materials, including thermoplastic or thermosetting polymer matrix, as well as to determine the effect of micro or nano-composite added to polymers (Mei and Chung, 2001; Zhang *et al.*, 2006). DSC is an effective tool for examining the change in the specific heat after reinforcing nano-particle to the polymer matrix. Study reported for DSC analysis reveals that 0.01% graphene to polyester and 0.01% graphite improved the specific heat to 334% and 264% respectively (Bastiurea *et al.*, 2014). The thermal analysis can be helpful for those application areas where it is required to determine the thermal degradation of the polymer or resins (Santana *et al.*, 2011). One study highlighted that increase in the Barium Titanate as filler to the Poly (Methyl Methacrylate) matrix from 5% to 20% resulted in the increase in the thermal degradation (Elshereksi *et al.*, 2014). It can be understood from the thermal analysis that for some of the polymer, the specific type of filler contributed to the thermal degradation and change in the rheological properties (Liu and Lelievre, 1992). Modulated Temperature Differential Scanning Calorimetry (MTDSC) is the variant of DSC, the MTDSC is an

Fig. 1 Waste management hierarchy for plastic recycling. Reproduced from Papargyropoulou, E., Lozano, R., Steinberger, J.K., Wright, N., bin Ujang, Z., 2014. The food waste hierarchy as a framework for the management of food surplus and food waste. *Journal of Cleaner Production* 76, 106–115.

evaluation technique which can analyses the effect of temperature and other thermal properties on the specific heat of the sample. It was established that the heat capacity is more strongly dependent on the temperature than the thermal conductivity. Crystallinity is the one of the thermal analyses that can be helpful to check the affectivity of the fiber on the polypropylene composites (Panda and Das, 2007). lignocellulosic fiber obtained from orange wood reinforced to polypropylene resulted in the improved crystallinity as analyzed by DSC (Reixach *et al.*, 2015). It was reported for DSC that hydrophobic drug – phenacetin added to the polyethylene glycol (PEG) at defined proportion of 1–4:1 was liable to produce a solid dispersion phase (crystalline structure) (Gerasimov *et al.*, 2013). In relation to the constitute variation analyses of polymers, DSC is applicable to the examinations of the thermal variations occurring in polymer arrangements during chemical reactions (e.g. polymerization), oxidative degradation, vaporization, sublimation and desorption. The DSC results are justified by the way of X ray diffraction, scanning electron microscopy and transmission electron microscopy to explore the affectivity of the nanoparticle on the polymer nano-composite (Corcione and Frigione, 2012).

The reported literature highlights that tertiary recycled thermoplastic are processed further for quaternary recycling process (to lastly use the thermoplastic material for energy recovery by burning/decomposition). Since quaternary recycling produces harmful environmental pollution, it was considered as least favorable recycling technique. In the present study, DSC analysis of nano-composite reinforced tertiary recycled thermoplastic have been investigated in term of heat capacities to be applied as the nano-porous material in energy conversion or storage unit instead of quaternary recycling.

Materials and Method

In the present study, nano-porous material developed by reinforcement of nano-particle into thermoplastic matrix though extrusion process, undergone endothermic and exothermic reactions to evaluate their capacities of heat release or heat gain. Some of the thermoplastic namely; ABS, PA6, PVC, PLA, HDPE and LDPE were reinforced with different nano-particles were investigated though differential scanning calorimeter (DSC). DSC analysis were conducted on ABS reinforced with nano-sized Aluminum (Al) particle, PA6 reinforced with nano-sized iron (Fe) metal, PVC reinforced with nano-sized Hydroxyapatite (HAp), PLA reinforced with nano-sized HAp, HDPE with nano-sized Silicon carbide + Alumina ($\text{SiC} + \text{Al}_2\text{O}_3$) and LDPE reinforced with $\text{SiC} + \text{Al}_2\text{O}_3$.

The twin screw extrusion (TSE) is advancement in the extrusion technology which is used for providing excellent mixing/reinforcement of nano or micro-sized particles to thermoplastic matrix. The reinforcement of nano-sized material to the thermoplastic matrix ensures the preparation of nano-porous materials. In the present study, co-rotating type screw extrusion was used for reinforcement of nano-sized particles to thermoplastic matrix.

Experimentation

Initially virgin thermoplastic material was processed to pre-heating temperature (e.g., 250°C for ABS) to remove any thermal history associated with thermoplastic material. The TSE was used for mixing/reinforcing the nano-particle with thermoplastic material. Again the mixed composition was treated to pre-heating for removing thermal histories. Next the material was put in DSC chamber and processed in continuous cycles of endothermic (e.g., 30–250°C for ABS) and exothermic reactions (e.g., 250–30°C for ABS). Then results were interpreted by software integrated with DSC setup to investigate the outcomes of DSC. Fig. 2 shows detailed experimentation to investigate the effect of nano-particles on thermoplastic matrix.

Table 1 shows Operating condition of DSC for each of the material. The operating condition was selected by their nature of decomposition. The temperature ranges are selected in between the decomposition temperature of each of the thermoplastics under 50 ml/min N_2 gas supply and 2 alternating heating and cooling cycles.

Fig. 2 Steps involved in DSC analysis of nano-particle reinforced thermoplastics.

Table 1 Processing condition for thermoplastic material through DSC

Materials	Reinforcement of nano-particle	Endothermic reaction	Exothermic reaction
ABS	40%Fe	30–250°C	250–30°C
PA6	40%Fe	30–250°C	250–30°C
PA6	30%TiO ₂	30–300°C	300–30°C
PLA	10%HAp	30–170°C	170–30°C
PVC	10%HAp	30–210°C	210–30°C
HDPE	10%SiC + Al ₂ O ₃	30–300°C	300–30°C
LDPE	10%SiC + Al ₂ O ₃	30–150°C	150–30°C

**Fig. 3** DSC Curves of Virgin ABS and ABS-40%Fe.

Results and Discussion

Different studies of ABS, PLA, HDPE, LDPE, PA6 and PVC thermoplastic under different reinforcement have been investigated to check the applicability of nano-porous material to use as energy conversion and storage applications.

ABS

ABS is common thermoplastic which is amorphous in nature and having high impact resistance, heat resistance and toughness, low thermal conductivity to potentially applicable in civil engineering field. The high moulding behavior of ABS makes it one of the best thermoplastic for possible preparations of nano-porous material in energy conversion and storage units. **Fig. 3** shows DSC curves of virgin ABS and ABS-40%Fe.

As ABS undergone DSC testing under controlled N₂ gas supply within endothermic and exothermic reactions, it was observed at glass transition peak that virgin ABS has taken 1.00 J/g energy for temperature transition of 93.34–109°C whereas ABS-40%Fe was taken 0.78 J/g energy for temperature transition of 93.67–109.82°C. The most interesting fact is appeared here that Fe reinforcement in the ABS matrix lead to the less energy requirement for transition between the specified temperature. In the second cycles it was recorded that thermoplastic material was unstable (thermally) after one heating and one cooling cycle as energy

integral of virgin ABS was reduced from 6.92 to 3.46mJ whereas energy integral of ABS-40%Fe was reduced only to small difference from 5.45 to 5.21mJ. It was also observed that energy requirement of virgin ABS was reduced from 1.00 J/g to 0.50 J/g but ABS-40%Fe was stable was reduced only from 0.79 J/g to 0.75 J/g. These prediction of DSC analysis reveals that reinforcement of Fe nano-particle has stabilized the ABS thermoplastic and can be applicable for preparation of nano-porous material for energy conversion and storage.

PA6

PA6 also known and poly-caprolactam or nylon 6 is a semi-crystalline polymer which has excellent mechanical, thermal properties but poor bio-degradability and generally not preferred for recycling processes. PA6 is a synthetic polymer which is extensively used in textiles, automobile and sportswear applications because of their durability and strength. As PA6 has the limitations for recycling purpose, so that it can be best use as the energy conversion and storage unit because it has excellent specific heat capacities.

PA6-30%TiO₂

Titanium oxide (TiO₂) is also known as titania is a natural oxide of titanium which is largely used for paint preparations. Since TiO₂ is having good bio-degradability and excellent electrical properties so that this is a potential material for recycling of polymeric waste for energy conversion and storage applications. As PA6 with 30%TiO₂ undergone DSC testing under controlled N₂ gas supply within endothermic and exothermic reactions. It was observed at melting transition peak that virgin PA6 was taken 625.52 J/g energy for temperature transition of 216-30-229.27°C whereas PA6-30%TiO₂ was taken 546.29 J/g energy for temperature transition of 217.79-229.16°C. The most interesting fact is appeared here that TiO₂ reinforcement in the PA6 matrix lead to the less energy requirement for transition between the specified temperature. In the second cycles it was recorded that virgin material was unestablished after one heating and one cooling cycle as energy integral energy of virgin PA6 was reduced from 625.52 to 490.24mJ whereas integral energy of PA6-30%TiO₂ was reduced only to small difference from 393.48 to 306.59mJ. It was also observed that energy requirement of virgin PA6 was reduced from 62.55 J/g to 49.05 J/g but PA6-30%TiO₂ was stable was reduced only from 46.29 J/g to 36.07 J/g (See Fig. 4). These prediction of DSC analysis reveals that reinforcement of TiO₂ nano-particle was stabilized the PA6 thermoplastic and can be applicable for preparation of nano-porous material for energy conversion and storage.

Fig. 4 DSC Curves of Virgin PA6 and PA6-30%TiO₂.

Fig. 5 DSC Curves of Virgin PA6 and PA6-40%Fe.

PA6-40%Fe

The next case study was the reinforcement of nano-sized Fe metal powder to the PA6 thermoplastic with 40% by weight. As PA6 with 40%Fe undergone DSC testing under controlled N₂ gas supply within endothermic and exothermic reactions. It was observed at melting transition peak that virgin PA6 was taken 69.17 J/g energy for temperature transition of 213.13–227.79°C whereas PA6-40%Fe was taken 31.70 J/g energy for temperature transition of 209.87–225.05°C. The most interesting fact is appeared here that Fe reinforcement in the PA6 matrix lead to the less energy requirement for transition between the specified temperature. In the second cycles it was recorded that virgin material was unestablished after one heating and one cooling cycle as energy integral energy of virgin PA6 was reduced from 539.55 to 456.34 mJ whereas integral energy of PA6-40%Fe was reduced only to small difference from 209.87 to 146.77 mJ (See Fig. 5).

PLA

PLA is also known as polylactide is a semi crystalline, bio-degradable and bio-active polymer which has wide application prospective in the 3D printing, injection moulding, film and sheet casting, spinning and biomedical implants fields. Although PLA has the wide bio-degradability but waste or contaminated PLA is still a dangerous aspects of environment and need to be minimized by apply it to in the energy conversion and storage. The next case study was the reinforcement of nano-sized Hap powder to the PLA thermoplastic with 10% by weight. As PLA with 10%HAp undergone DSC testing, it was observed at melting transition peak that virgin PLA was taken 19.27 J/g energy for temperature transition of 152.40–158.26°C whereas PLA-10%HAp was taken 10.88 J/g energy for temperature transition of 151.94–160.02°C. The most interesting fact is appeared here that HAp reinforcement in the PLA matrix lead to the less energy requirement for transition between the specified temperature. In the second cycles it was recorded that virgin PLA material was unestablished after one heating and one cooling cycle as energy integral energy of virgin PLA was reduced from 154.17 to 106.18mJ whereas integral energy of PLA-10%HAp was reduced only to small difference from 108.82 to 107.43mJ only. Similarly a large drop of normalized energy was observed (In one heating and cooling cycle) in the case of PLA where it was reduced from 19.27 J/g to 13.27 J/g whereas in case of PLA-10%HAp it was dropped only from 10.88 J/g to 10.74 J/g (See Fig. 6). This exhibited nature of PLA after 10%HAp reinforcement shows the affinity of its heat capacity for potential use in energy conversion and storage process.

PVC

PVC is most widely used synthetic polymer after polyethylene and polypropylene having the low degree of recyclability, because it possesses huge amount of pollution by heat treatment. PVC are heat stabilize by crucial additive of metal or ceramic. As PVC

Fig. 6 DSC Curves of Virgin PLA and PLA-10%HAp.

having low degree of recyclability, so this can be potentially applicable for use as the energy conversion units. As PVC with 10% HAp undergone DSC testing, it was observed at melting transition peak that virgin PVC was taken 19.52 J/g energy for temperature transition of 145.29–164.27°C whereas PVC-10%HAp was taken 19.02 J/g energy for temperature transition of 147.49–164.64°C. The most interesting fact is appeared here that HAp reinforcement in the PVC matrix lead to the less energy requirement for transition between the specified temperature. In the second cycles it was recorded that virgin PVC material was unestablished after one heating and one cooling cycle as energy integral energy of virgin PVC was reduced from 171.76 to 107.13 mJ whereas integral energy of PVC-10%HAp was reduced only to small difference from 159.73 to 154.75 mJ only. Similarly a large drop of normalized energy was observed (In one heating and cooling cycle) in the case of PVC where it was reduced from 19.52 J/g to 12.17 J/g whereas in case of PVC-10%HAp it was dropped only from 19.02 J/g to 18.42 J/g (See Fig. 7).

HDPE

HDPE is made from petroleum products and is largely used in the production of plastic bottles, corrosion resisting pipes and plastic bags. HDPE is an excellent polymer due to its moulding capabilities. Thus HDPE is a best suited material for forming, extrusion, injection moulding and 3D printing. SiC and Al₂O₃ are ceramic material best known for reinforcement material in plastic matrix for recycling purposes. It was observed at melting transition peak that virgin HDPE was taken 110.97 J/g energy for temperature transition of 120.99–135.98°C whereas HDPE-10%SiC + Al₂O₃ was taken 90.07 J/g energy for temperature transition of 123.32–133.79°C. In the second cycles it was recorded that virgin HDPE material was unestablished after one heating and one cooling cycle as energy integral energy of virgin HDPE was reduced from 654.71 to 515.42 mJ whereas integral energy of HDPE-10%SiC + Al₂O₃ was reduced only to small difference from 405.34 to 395.83 mJ only. Similarly, in the case of HDPE, it was reduced from 110.97/g to 87.26 J/g whereas in case of HDPE-10%SiC + Al₂O₃, it was dropped only from 90.07 J/g to 87.96 J/g (See Fig. 8).

LDPE

LDPE is polymer made from monomer ethylene which is largely used for the corrosion resistance surfaces, flexible trays, juice and milk carton, plastic wrap etc. Since LDPE is highly chemical resistive so that tertiary recycling of it is practically uneconomical and hence applicable for preparation of porous materials for use in energy conversion and storage. It was observed at melting transition peak that virgin LDPE was taken 92.62 J/g energy for temperature transition of 122.89–134.60°C whereas

Fig. 7 DSC Curves of Virgin PLA and PVC-10%HAp.

Fig. 8 DSC Curves of Virgin HDPE and HDPE-10%SiC + Al₂O₃.

Fig. 9 DSC Curves of Virgin LDPE and LDPE-10%SiC + Al₂O₃.

LDPE-10%SiC + Al₂O₃ was taken 66.84 J/g energy for temperature transition of 122.07–133.48°C. In the second cycles it was recorded that virgin LDPE material was unestablished after one heating and one cooling cycle as energy integral energy of virgin LDPE was reduced from 259.35 to 233.54 mJ whereas integral energy of LDPE-10%SiC + Al₂O₃ was reduced only to small difference from 213.89 to 201.50 mJ only. Similarly a large drop of normalized energy was observed (In one heating and cooling cycle) in the case of virgin LDPE where it was reduced from 92.62/g to 83.81 J/g whereas in case of LDPE-10%SiC + Al₂O₃, it was dropped only from 66.84 J/g to 62.97 J/g (See [Fig. 9](#)).

Summary

Recycling of thermoplastic is a critical issue which can be a source of hazard if proper scientific methods are not applied. Among recycling techniques, quaternary recycling is most dangerous for environment as it produces large pollution in forms of fumes or gases. The quaternary recycling can be replaced with use of those thermoplastic in some useful application like; energy conversion and storage. As thermoplastic has the moulding capabilities, so addition of nano-sized reinforcements of metallic/ ceramic powder helps in heat stabilization to their matrix and can enhance the specific heat capacities (to be applied as energy conversation and storage by heating). In the present study, DSC analysis of nano-composite reinforced tertiary recycled thermoplastic have been investigated in term of heat capacities of material in energy conversion or storage unit instead of quaternary recycling. The study suggested that addition of nano-particle enhanced the tendency of heat retaining after a series of heating and cooling cycles, thus this is practically verified that those polymer can be best used as energy conversion and storage materials.

Introduction

3DP, Energy Conversion, GR, Twin, Feed Stock, FDM

3D printing, better known as “additive manufacturing”, forms the object by successive layers of materials for different application areas. 3D printing has the potential/impact to transform manufacturing supply chain, distribution channel and business model (Singh *et al.*, 2018a,b,c). Commercially fused deposition modeling (FDM), stereo lithography (SLA), inkjet printing, selective laser sintering (SLS), digital light manufacturing (DLP), selective laser melting (SLM), electronic beam melting (EBM) and laminated object manufacturing (LOM) are some of the commonly used 3D printing technologies for assembly, repair/maintenance, rapid tooling, waste management, energy storage etc. (Kumar *et al.*, 2017, 2018b,c; Singh *et al.*, 2016). Energy transformation, also termed as energy conversion, is a process for converting one form of energy into another form, for example a combustion process is used to convert chemical energy into thermal energy. In physics, energy is a quantity that provides the capacity to perform many actions – think of lifting or warming an object. Energy in many of its forms may be used in natural processes, or to provide some service to society such as heating, refrigeration, lightening or performing mechanical work to operate machines. For example, in order to heat your home, your furnace can burn fuel, whose chemical potential energy is thus converted into thermal energy, which is then transferred to your home’s air in order to raise its temperature. Thermoplastics are basically low cost material which is best suited for energy conversion where lightweight, design flexibility and intricate shapes are essential. But some of the hindrances are observed for polymeric material to use as energy conversion material as those having poor solid state morphologies, mismatch of energy gap and poor conductivities (Sun *et al.*, 2014). Organic semiconductor based photovoltaic devices offers the possibility of manufacturing low cost photovoltaic technology that can be 3D printed by roll to roll printing techniques. Existing organic photovoltaic devices are currently limited to solar power conversion efficiencies of 3%–5% (Shaheen *et al.*, 2005). Graphene is two dimensional materials which has extraordinary material characteristics like: High Young’s modulus, thermally and electrically superconductive (high mobility of charge and electron), surface insulating behavior and large aspect ratio for prototype fabrication. Graphite is a low cost raw source for extraction of graphene. Graphene generally extracted via different methods of processing like; chemical vapour deposition (CVD), micromechanical exfoliation, and ball milling etc. (Park and Ruoff, 2009; Su *et al.*, 2011; Calderon- Ayala *et al.*, 2017).

FDM processes as a 3D printing technique with feedstock prepared on twin screw extrusion process and is the best alternative for production of electrically conducting nano-porous polymeric composite materials for energy conversion and storage (Kumar *et al.*, 2018a). To introduce graphene reinforced polymeric composite as energy conversion material, it must fulfill the requirement of strong interfacial interactions of graphene and polymers so that maximum electrical and thermal conductivities should be achieved (Cui *et al.*, 2016). There are varieties of screw extrusion processes available for producing feedstock filament for FDM. Single screw extrusion is a conventional process for producing feedstock filament but defects like, tiny pores, blow holes, non-mixing are the major problems associated with this process. Twin screw extrusion has emerged as an advanced technique for producing feedstock filament free from defects. Twin-screw extruder are capable to ensure mixing, shearing, cooling, heating, compressing, transporting, shaping, pumping, etc. with very high level of flexibility. The main advantages of twin-screw extruders (intermeshing co-rotating) are their exceptional mixing capability that gives the remarkable characteristics to extruded products. In the twin-screw extrusion process, the raw materials may be solids (granules, powders & flours), slurries, liquids, and possibly gases (John *et al.*, 2014; Wang *et al.*, 2016a,b). FDM is the melt extrusion process in which robotic device is works on the CNC programming to control the heating and movement of the filaments. The extruded material through the nozzle head is directed on the print bed and immediately hardened to ensure the part fabrication. To ensure the better dimensional stability of the component formed it is required to process the printing below the melting point of the substrate. Properties of parts produced by the FDM is the function of the filament preparations, extrusion is the basic process which are uses for the preparation of feedstock filaments. Extrusion processes are largely used for the production of useful inputs for additive manufacturing techniques. The requirement of these processes is increasingly important from sustainability viewpoints when targeting waste management of thermoplastic materials. Mechanical properties of FDM fabricated parts are highly dominated by their filament processing. the mechanical sustainability of the fabricated parts are dependent upon the nature of processing of the initial component (grinding, extrusion etc.). Barrel temperature, rotational speed and torque are some of the input variable during the filament processing which largely affects the mechanical sustainability of the FDM fabricated parts (Singh *et al.*, 2017a, 2018d, 2017b; Singh and Kumar, 2017c; Singh *et al.*, 2017d). FDM as 3D printing technique is most economical way of producing 4D thermoplastic composite reinforced with nano-particle with use of extrusion process for development of energy conversion and storage devices. In the present study, the concept of 4D printing by use of FDM has been delivered for converting electrical energy into mechanical energy.

Application of Nano-Porous Materials for Printing of Transducer

As per Maxwell's right-hand thumb rule, assume current carrying wire in right hand, then thumb's direction denotes the direction of the current flow and the direction in which hand is being wrap represents the direction of magnetic lines of forces. If we take two different current carrying conductors, then two cases will emerge: In the first case flow of current in both conductors is in same direction and in second case flow of current in both conductors is in opposite directions. As reflected in Fig. 1(a and b), if the current of two current carrying conductor flow in a same direction then magnetic lines of forces will attract to each other and there will be contraction. Similarly, if the current of two current carrying conductors flow in opposite direction then magnetic lines of forces will repel each other and there will be an expansion.

As per Biot-Savart law, the magnetic field (B) generated by steady current (I) where charge is neither accumulate nor depleted at any point:

$$B = \frac{\mu_0 I}{4\pi} \int \frac{d\vec{l} \times \hat{r}}{r^2}$$

where vector $d\vec{l}$ is the vector line element with direction in the same sense as the current I , μ_0 is the magnetic constant, r is the distance between the location of $d\vec{l}$ and the location where the magnetic field is calculated, and $\hat{r}$ is a unit vector in the direction of r . and r is distance from the wire.

The Ampere's law can be helpful to measure value of magnetic fields for infinitely long current carrying conductors. Magnetic field can be measured as:

$$B = \frac{\mu_0 I}{2\pi r}$$

Proposed Application as Transducer

In actual field applications recycling of plastic waste is one of the serious problems. In the present study a novel method for recycling of plastic/ polymer waste has been proposed by use of this material for four dimensional printing applications. The idea is to use multi-jet (02) extrusion nozzles of fused deposition modeling setup for printing multi layers of conducting thermoplastic composite (like: Graphene reinforced thermoplastics) and non-conducting polymer waste (like ABS, Nylon6). The schematic (See Fig. 2) for same is given as under:

Now if current is passed in same direction between two parallel conductors than by basic principle two conducting wires will generate magnetic field and will attract each other. Similarly when the direction of current between two parallel conductors is reversed they will experience repulsive force.

This basic principle has been used to develop new/in-house, 4D printing materials. With this multi material sandwiched component, just by changing the direction of current flow the component will change its thickness, because of change in magnetic field. Finally this will help to develop in-house transducer at very low cost and also lead to waste management of polymer materials.

Proposed Methodology for 4D Printing of Nano-Porous Material for Energy Conversion

The proposed method of 4D printing illustrated in 4D printing is an innovative route for conversion of electrical energy into mechanical work. 4D printing of nano-porous material can be processed by integrating established FDM and extrusion technologies. The detailed method of such 4D printing technique can be processed as (See Fig. 3):

Graphene is an extraordinary material that is now days used largely to produced nano-porous materials. Graphene also has inherent material characteristics like: Excellent thermal and electrical conductivities, high mechanical strength and etc. In the proposed method of

Fig. 1 Maxwell's right-hand thumb rule.

Fig. 2 Concept of 4D printing.

Fig. 3 Detailed methodology of 4D printing for energy conversion.

Fig. 4 Effect of graphene and infill density on thermal and electrical conductivities of ABS. Reproduced from: Kumar, R., Singh, R., Hui, D., Feo, L., Fraternali, F., 2018b. Graphene as biomedical sensing element: State of art review and potential engineering applications. Composites Part B: Engineering 134, 193–206.

4D printing for development of energy conversion unit a thermoplastic matrix will be used as main material. As acrylonitrile butadiene styrene (ABS) is having excellent molding stability so this can be selected as for fabrication of conducting as well as non-conducting layers. ABS is a non-conducting material, but when reinforced with nano-sized graphene into its matrix the excellent thermal as well as electrical conductivities can be achieved. As reported by Kumar *et al.* (2018b), thermal conductivities as well as electrical conductivities of ABS polymer matrix can be improved by reinforcement of graphene powder (See Fig. 4). There are two ways available for mixing of graphene into polymer matrix: Mechanical mixing and chemical mixing. The mechanical mixing is the process of mixing graphene into polymer matrix by using twin extrusion process in which granules of polymer matrix mixed with graphene through the compound screws of twin screw extrusion. In chemical mixing, granules of polymer and graphene are being treated under dissolution of chemical (As ABS is being dissolve in acetone solution). As study conducted, it was measured the electrical and thermal conductivities of graphene reinforced ABS mixed under chemical as well as mechanical mean. It is reported that chemical mixing of graphene reinforced ABS polymer matrix resulted in maximum electrical and thermal conductivities for ABS: Graphene ratio of 75:25 under 100% infill density. So it is clear from here that mixing of graphene into polymer matrix largely influences the electrical and thermal characteristics.

After mixing of graphene into polymer matrix it should be subjected to twin screw extrusion for preparations of feedstock filaments. It should be noted that twin screw extrusion is also used for mechanical mixing of graphene into polymeric matrix. After preparations of feedstock filaments, a CAD based model into STL file formatted must be prepared of required dimension on any design platform. The slicing will ensure the desired layers thickness and numbers of layers also. The energy conversion by this novel 4D printing will largely depend upon the number and thickness of additive layers. The FDM setup would be configured with at least two printing nozzles so that alternative layers of conducting and non-conducting material can be printed. The post processing in the ultrasonic chemical bath can be used as the post processing of the printed model to get best output. Finally, the printed part assembly to the main circuit of energy conversion unit lead to convert the electrical energy into some useful mechanical work. There are two types of mechanical motions can be achieved, one for contracting the structure when current in all 4D printed alternating layers flows in same direction, another for expanding the structures when alternating layers have current flow in reverse direction to each other (according to the Maxwell's right-hand thumb rule).

Summary

The proposed way of 4D printing for energy conversion has pointed out following consideration to be potentially applied in society.

- Printing of alternating layers of conducting and non-conducting materials by use of cost effective printing technology such as FDM is one of the innovative route for 4D printing.
- As established theories (Maxwell's right hands thumb rule, Lorentz force rule, Fleming's right hands rule etc.) suggested that current carrying material flowing in same direction will attract to each other and flowing in reverse direction will repel to each other, the proposed method of 4D printing has the great potential to use as the energy conversion tool in engineering applications.
- Graphene has the potential to be applied as the material for energy conversion and storage when reinforced into polymers matrix as it is having excellent electrical and thermal conductivity. On the other hand, nano-sized graphene is largely used for production of nano-porous material that has wider prospective in the energy conversion and storage fields.

Acknowledgement

The authors are highly thankful to Board of Research in Nuclear Science (BRNS) and manufacturing research lab (GNDEC, Ludhiana) for providing financial/technical assistance to carry out the research work.

Appraisal of E-Drought System Based on Object Oriented Approach

Dalibor Petković, University of Niš, Pedagogical Faculty in Vranje, Partizanska, Vranje, Serbia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Drought is a disaster which could be very harmful especially for agriculture sector. Drought could be classified as meteorological, hydrological, agricultural and economic. Management of water and agriculture could be indicated by drought monitoring. Therefore there is need for accurate estimation and monitoring of drought. However there is need to present drought characteristics by some indicator in order to track it. There are many drought indices which could be used for drought estimation (Heim, 2002; Keyantash and Dracup, 2002). Water surplus variability index (WSVI) is a drought index which incorporate precipitation and reference evapotranspiration (Gocic and Trajkovic, 2014a).

The Palmer Drought Severity Index (PDSI) has been widely used to monitor drought but its characteristics are more suitable for measuring droughts of longer timescales, and this fact has not received much attention (Zhao *et al.*, 2017). Due to severe drought events and disastrous impacts in recent decades, substantial efforts have been devoted recently to drought monitoring, prediction and risk analysis for aiding drought preparedness plans and mitigation measures (Hao *et al.*, 2017a). Various drought information systems have been developed with different indicators to provide early drought warning (Hao *et al.*, 2017b). Drought indices are widely used for drought monitoring (Tian *et al.*, 2018). Results in article (Liu *et al.*, 2018) suggested that solar-induced chlorophyll fluorescence (SIF) is better fit in early drought monitoring, especially over closure canopy, while Normalized Difference Vegetation Index (NDVI) is more feasible when drought lasted over a long time scale. Our findings in the study might provide deep insight into the utility of SIF in drought monitoring. In article (Mishra *et al.*, 2017) was presented that the Soil Water Deficit Index (SWDI) is an effective agricultural drought indicator and it provides continuity and introduces new spatial mapping capability for drought monitoring. In paper (Nourani and Molajou, 2017), hybrid application of two data mining was offered to discover affiliation between droughts and de-trend Sea Surface Temperature (SST). Temperature vegetation dryness index (TVDI) and crop water stress index (CWSI) are two commonly used remote sensing-based agricultural drought indicators (Bai *et al.*, 2017). Timely and accurate monitoring of the onset and evolution of drought are important to reduce losses from drought (Wu *et al.*, 2015). The drought characterization becomes possible with the initiation of the meteorological, agricultural and hydrological drought indices (Haied *et al.*, 2017). Agricultural drought is a complex and insidious natural hazard further complicated by crop impacts (Zhang *et al.*, 2017). Remote sensing can provide real-time and dynamic information for terrestrial ecosystems, facilitating effective drought monitoring (Zhang *et al.*, 2016). Drought can consequently have substantial effects on agriculture and socioeconomic activities that cause social crises and political problems (Cunha *et al.*, 2015). As soil moisture is of key importance in understanding the interaction between the atmosphere and Earth's surface, it can be used to monitor droughts (Park *et al.*, 2017).

The main objective of the study is design a new e-drought information system for the drought monitoring and estimation. The drought monitoring is based on based on soft computing methodology, adaptive neuro-fuzzy inference system (ANFIS) (Jang, 1993), which is suitable for the nonlinear data pairs where there is lack of data for some regions. The e-drought system is developed and analyzed by unified modeling language (Lethbridge and Laganier, 2005; Jacobson, 1993).

Methodology

Climatic Data

The used climatic data are from World Bank Database for European Union. The following climatic input are used:

- T_{min} - input 1,
- T_{max} - input 2,
- e_a - input 3,
- RH_{min} - input 4,
- RH_{max} - input 5,
- U_2 - input 6,
- P - input 7,
- n - input 8

Drought severity can be obtained by the estimating of the Water Surplus Variability Index (WSVI) (Gocic and Trajkovic, 2013, 2014b).

ET Calculation

In this study FAO Penman-Monteith equation is used for ET calculation based on presented weather data. Based on the FAO Penman-Monteith equation ET index is calculated according to the weather data: minimal and maximal air temperatures, minimal

and maximal relative humidity, average wind speed and solar radiation. The weather data is acquired from World Bank Database for European Union. The input weather parameters are listed as follows:

- (1) Maximum air temperature [$^{\circ}\text{C}$]
- (2) Minimum air temperature [$^{\circ}\text{C}$]
- (3) Maximum relative humidity [%]
- (4) Minimum relative humidity [%]
- (5) Average wind speed [m s^{-1}]
- (6) Solar radiation [$\text{MJ m}^{-2} \text{day}^{-1}$]

E-Drought Information System

Modeling of an e-drought information system should include different climatic factors which have impact of drought. In this study the e-drought system has eight climatic factors. Unified modeling language (UML) is used for the modeling and analyzing of the system. This is standard methodology which are used for different aspects of the system modeling. UML could be used for specification, visualization, construction and documentation of information system. UML is based on object-oriented concepts and it is suitable for system modeling in initial stage before coding by some programming language.

The most important thing is the modeling process is to identify system actors or users and use cases. The use case presents one sequence of action which produce some visible. The use case is used to define system behavior. Therefore by used cases desired behavior of system could be presented. However the desired behavior might not be achieved in the final stage. The use case models could be used for modeling of the whole system or to model each part of the system.

Results

Use Case Diagrams of the E-Drought Information System

Fig. 1 shows the main use case diagram of the e-drought information system. As can be seen there are two actors in the system: users and WSVI-module. The users could import of climatic data. The WSVI-module is responsible for drought monitoring based on the climatic data. WSVI is estimated based on ANFIS model which is incorporated in the WSVI-module.

Fig. 2 shows the use case of importing of climatic data by user. The use case has eight activities. Each of the activity belongs to specific input parameter which is important for WSVI estimation and monitoring.

Fig. 3 shows the use case of calculating of drought index. As can be seen the use case has three activities. These activities is based on ANFIS training and testing procedure based on the given input/output climatic data pairs. The first activity is ANFIS training procedure. The second activity is ANFIS testing procedure. And the final activity should provide the drought output results based on the WSVI index.

Statistical Results

ANFIS models are trained and tested by the climatic data based on the calculated WSVI index. According to the results one can estimate the correlations between climatic data and drought index. If the ANFIS training results are small than the correlation between the parameters will be strong. **Table 1** shows that the parameter P has the strongest correlation since the training errors are the smallest for this input parameter. Combination of parameters $T_{\min}/e_a$ is the combination of two parameters which has the strongest correlation with drought index. Also $T_{\min}/e_a/P$ is the combination of three parameters which has the strongest correlation with drought index.

Fig. 1 Main use case diagram of the e-drought information system.

Fig. 2 Use case: Importing of climatic data.

Fig. 3 Use case: Calculating of drought index.

Table 1 ANFIS correlation errors between climatic data and drought index

Climatic parameters	Training error	Checking error
P	0.9677	0.9622
T_{min}/e_a	0.9130	1.0028
$T_{min}/e_a/P$	0.8140	1.0960

Conclusion

Designing of new information systems for drought monitoring could be very important for agriculture and water management systems. In this study an object-oriented approach was applied for e-drought monitoring system. The system structure is incorporated with ANFIS methodology since drought index is calculated based on acquired input/output climatic data. The system is able to estimate the current values of drought based on imported climatic data by user.

Bamboo Fiber as Fillers for Polypropylene-Nanoclay via Injection Molding

Mohd H Othman, Tun Hussein Onn University of Malaysia, Johor, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Recently, in the polymer science field of research, composites made from the combination of polymer and natural fiber were becoming an uprising interest exploration. The fact that natural fibers are naturally economical solution due to its low density with certain useful possessions such as biodegradable and non-abrasive. Typical natural fibers are categorized into three groups, which are mineral, animal and plant, based on their origin. Some examples of plant natural fibers are cotton, flax, jute, coir, sisal and bamboo. Some of these fibers provide high stiffness, yet they are relatively sensitive to moisture with high variability of length and diameter. The high moisture sensitivity could overcome with certain treatment. This treatment could increase the cost due to additional process involved, nonetheless it is still affordable and cost effective (Wallenberger and Weston, 2003).

According to Food and Agricultural Organization (FAO) of the United Nations website, a thematic study had been prepared in the framework of the Global Forest Resources, which describe several information about bamboo, such as the extent of bamboo, the ownership, characteristics of bamboo growing stock, diversity of species, removals (poles and fuel wood) and value of bamboo removals and products (Lobovikov *et al.*, 2007). In this article, bamboo fiber was used as the reinforcement material in the polypropylene-nanoclay system. This fiber can be used as reinforcement in polymer, with the aid of compatibilizer, with consideration of type of product, mechanical properties, processing and environmental aspects. To support this statement, according to Bonse *et al.* (2010), adding bamboo fiber in a polymer system with the aid of compatibilizer will provide certain advantages on flexural strength and modulus, as well as tensile strength. However, there are drawbacks such as decrement of elongation at break and energy to break-typically define as area under the stress-strain curve. Optimum quality of mechanical bamboo pulps also could be obtained with a higher fiber yield, less broken with more slender fibers, with regard to proper treatment and characterization monitoring (Ashaari *et al.*, 2010).

Nanocomposites comes from a combination of several materials, whereby the matrix of this advanced mixture was reinforced with one or more nano size material. Usually by adding the nanomaterial, some properties could be improved. Recent nanocomposites applications have rapidly in demand and attracting manufacturing industries to revalue their material usage and consumption. One of the examples of nanocomposites is polypropylene-nanoclay. This blend was selected based on their good properties, clear processing and wide potential usage (Othman *et al.*, 2014b), even though the effects of processing conditions on nanofillers dispersion towards the outcomes should be taken into consideration (Rajesh *et al.*, 2012). Furthermore, this blend could be prepared through direct intercalation, whereby the preparation of nanocomposites by using this method was better than in situ or chemical compounding methods as per it is well-matched with present mass produce industrial and manufacturing process (extrusion/injection molding) as well as environmentally friendly because no solvents involvement (Ray and Okamoto, 2003).

Injection molding was chosen as the processing method since it was parallel with major plastic manufacturing industry. It can produce massive quantity of product in practical lead time, with cost effective gains. However, this process could produce numbers of defects and it is difficult to control the outcome consistently (Dumitrescu *et al.*, 2005). Noted that each of the processing conditions is reliant on each other, hence, facts about the processing optimization will assist the production to yield more productivity, cost savings and quality results (Mehat and Kamaruddin, 2011). One of the technique of process optimization is Taguchi method. A review had been summarized regarding research that used this approach with encouraging findings (Mehat, and Kamaruddin, 2012). For instance, an optimization process has been performed toward snap fit samples by using Taguchi method (Othman *et al.*, 2014a). However, beside optimization, analysis regarding the melt flow behavior also need to be carried out due to the existence of filler may produce interfacial adhesion issues with resistance to polymer flow (Liang *et al.*, 2015).

Material Preparation

There are four major components to prepare this feedstock for injection molding process. The components are polypropylene as the matrix, compatibilizer (polypropylene-grafted-maleic-anhydride), and nanoclay with bamboo fiber as filler. Typically the content of polypropylene and bamboo fiber will be manipulated. The type of polypropylene chosen for this system was homopolymer. To prepare this mixture of polypropylene-nanoclay-bamboo fiber, three different formulations were proposed. Table 1 shows the portion of each formulation, whereby 0 wt%, 3 wt% and 6 wt% of bamboo content were proposed. Polypropylene-grafted-maleic anhydride was selected as the compatibilizer, used in this mixture preparation. The weight percentage was set permanently at 15 wt%, the same setting of the nanoclay at 1 wt%. This fixed setting was decided based on previous research (Othman *et al.*, 2017a,b). The bamboo fibers first need a pre-heating process by using a convection oven. The suggested temperature was between 110 and 120°C temperature. The mixing process of polymer nanocomposite could be executed by using a twin screw laboratory type compounder. The mixtures need to be transformed into small pellets using used pelletizer with recommended diameters from 1.0 to 4.0mm for ease an injection molding process.

Optimizing Injection Molding Processing Condition

An injection molding machine was used to produce the injected molded samples for observation and evaluation. In this case, melt flow index (MFI), flexural strength, shrinkage and warpage were monitored as the outcomes. The processing conditions selected for control were melting temperature, packing pressure, screw speed and filling time. Three levels for each processing conditions were set to be optimized through the Taguchi method (signal to noise ratio assessment) based on level L_93^4 . The process condition settings based on orthogonal array L_93^4 were shown in Table 2.

The effect of the properties and defect with optimum processing condition of polypropylene-nanoclay with fiber bamboo as fillers had been analyzed, whereby through Taguchi optimization method, the maximum value of signal to noise ratio had been selected. These signal to noise ratio values were used to select which processing condition level that should be selected to produce higher value of the melt flow index and flexural strength, with the minimum value of warpage and shrinkage. Optimum results could be attained by using the optimum processing condition.

Table 3 shows the optimum processing condition for the melt flow index. The setting of formulation 3 wt% of bamboo content, the best combination processing condition for optimizing the value of MFI were 170°C for melt temperature, 35% of packing pressure, 30% of screw speed and 3 s for filling time. These settings could produce 21.07 g/10 min for the value of MFI. For the 6 wt% of bamboo content, the optimum combination processing condition for maximizing the value of MFI were 170°C for melt temperature, 40% of packing pressure, 30% for of screw speed and 1 s for filling time. Table 3 also shows that the additional of 3 wt% of bamboo will produce higher melt flow index.

Table 4 shows the optimum processing condition for flexural strength. As described in data analysis earlier, the highest value of signal to noise ratio indicate the best setting for the processing condition or factor. From the results in Table 4, the increment of bamboo filler shall make the specimen more flexible, since the flexural strength was increased. As for the best processing condition for 3 wt% formulation of bamboo content, the optimum setting were melt temperature at 165°C, packing pressure at 35%, screw speed at 30% and the filling time was at 1 s. The similar processing conditions were used for formulation 6 wt% of bamboo content accept the filling time increased to 2 s. By using this setting, the flexural strength could increase by 7.741 N (with the additional another 3 wt% content of bamboo filler).

Table 1 Polypropylene-Nanoclay-Bamboo fiber portion for each formulation

Formulation	Bamboo content	Polypropylene content	Compatibilizer content	Nanoclay content
1st formulation	0 wt%	85 wt%	15 wt%	1 wt%
2nd formulation	3 wt%	81 wt%	15 wt%	1 wt%
3rd formulation	6 wt%	79 wt%	15 wt%	1 wt%

Table 6 Optimum processing condition for warpage

Bamboo content	Melt temperature (°C)	Packing pressure (%)	Screw speed (%)	Filling time (s)	Maximum warpage (mm)
0 wt%	165	40	35	2	0.004
3 wt%	165	35	30	1	0.004
6 wt%	165	35	30	2	0.004

Note: Othman, M.H., Hasan, S., Khamis, S.Z., Ibrahim, M.H.I., Amin, S.Y.M., 2017b. Optimization of injection molding parameter towards shrinkage and warpage for polypropylene-nanoclay-gigantochloa scortechinii nanocomposites. Procedia Engineering 184, 673–680.

Tables 5 and 6 shows the optimum processing conditions for controlling shrinkage and warpage, respectively. Based on the outcomes, there were not so much significant effect between the increment of bamboo content and the result of shrinkage and warpage. For instance, the setting for 3 wt% of bamboo content produced 0.0067% of shrinkage, the same results as the setting for 6 wt%. Moreover, the shrinkage value for the processing conditions also almost similar accepts filling time. Therefore, it is advisable to take the shortest time for productivity and high yield purposes.

Bamboo Fiber as Fillers for Polypropylene-Nanoclay

Based on the results after optimization, the addition of bamboo fiber as filler could increase the value of MFI and flexural strength, and at the same time could maintain the quality of the injected molded product by holding the value of shrinkage and warpage. As for the best processing condition, it is proposed to use 6 wt% formulation of bamboo content, the optimum setting were melt temperature at 165°C, packing pressure at 35%, screw speed at 30% and the filling time was at 1 s. By using this setting, a promising opportunity was provided to improve the quality of products made from this blend, via injection molding process. Not only that, adding bamboo fiber in a polymer system with the aid of a compatibilizer provides sufficient flexural modulus and tensile strength too (Bonse *et al.*, 2010). Via injection molding, many parts with massive quantity could be manufactured with minimum defects and higher productivity. The findings of this innovation could be useful for more detailed studies and put forward as a guideline for those who want participant or enhance the injection molding process in the future.

 ξ Damping loss factor
 ω Frequency at harmonic motion
 ω/ω_n Normalized frequency
 ω_n Natural frequency at harmonic motion

Introduction

Generally, most of the mechanical, civil, naval, aerospace, air-conditioning, and construction systems are subjected to excitations that induce vibration energy. These vibration problems are usually undesirable and they have the potential to damage a system and finally make it fail. To avoid this problem, therefore, it is very important to develop vibration isolation systems to reduce or dissipate the vibration energy from transmitting to other places such as the base structure, structure body, etc.

A common annoying noise in a building is from the vibration of machines located on the floors or walls, respectively. Many engineers agree that the best place to locate a vibrating machine is on the ground floor; however, this does not solve the annoying noise problem, which emanates from the machine itself whilst it is in operation. This problem is found in rotating machines such as pumps, compressors, engines, blowers, and many more. To solve the problem, vibrating machines have been placed on the top floor or mounted on the roof. However, this does not solve the problem of vibration in a building because mechanical vibrations can be transmitted over long distances, and can also cause the building structure to vibrate, and can sometimes be transmitted hundreds of feet from the vibration source. This has been proven in a few cases involving building structures where the buildings have been damaged because of the vibration problem.

For example, in Korea, a five-story department store in Sampoong City collapsed due to the impact of vibration in 1995. Fig. 1 shows the five-story store before and after collapse. This disaster killed more than 500 people and injured over 900.

Fig. 1 Structural failure due to vibration at sampoong five-story department store: (a) before collapse and (b) after collapse. Koreanstandardtime, 2015. Available at: <http://koreanstandardtime.tumblr.com/tagged/sampoong-department-store> (accessed 15.03.15).

The problem occurred because the air-conditioning system was placed on the roof without any isolator between it and the roof structure. The uncontrolled vibrations caused cracking to the support column and the whole building's structure. This constant vibration generated by the air-conditioning system caused a big crack, which eventually widened, leading to a critical failure, and finally the building collapsed and many people died (Koreanstandardtime, 2015).

In another incident, in 2013, a factory building collapsed in Dhaka, Bangladesh, killing more than 1000 workers. The building was initially designed for office purposes, not to be a factory. According to the investigation, the investigator concluded that the illegally constructed upper floors were a source of the disaster. Large power generators had been installed on the upper floors and hence injected great vibration input power to the floor structure and finally caused structural failure. This is one of the worst disasters involving building structure collapse due to the vibration phenomenon. Fig. 2 shows the situation in that particular disaster (Theguardian, 2015).

Therefore, the vibration effect in buildings needs to be taken seriously to avoid disasters such as this happening again, which means vibration isolators need to be used to reduce or block unwanted vibration from influencing the building structure itself.

Vibration Control

Vibrations have undesirable effects on human quality of life and also on our material goods. In general, a very useful strategy to reduce vibrations is to reduce or block the propagation path between the source and receiver. Fig. 3 shows the general vibration control strategy between three components, which are the source, the transmission path, and the receiver. The source is a mechanical or fluid disturbance that is generated internally by the machine because of misalignment, unbalance, torque pulsations, poor gear meshing, fan blade passing, etc. Transmission path is the part or structural or airborne path by which the disturbance is transmitted or transferred from source to receiver. Receiver is the responding system, likely a mechanical system, which is structural, and which generally has natural frequencies that have a big potential to be excited by vibration frequencies generated by the source. In practice, there are three types of vibration control strategies: passive vibration control, semiactive vibration control, and active vibration control.

Passive vibration control is a one of a number of vibration control strategies involving the modification of the stiffness, mass, and damping values at source or receiver. The modification takes place via basic structural changes or including additional passive elements at the transmission path, as illustrated in Fig. 4.

Fig. 2 Structural failure due to great vibration input power to the floor structure in Dhaka, Bangladesh: (a) front view and (b) side view. Theguardian, 2015. Available at: <http://www.theguardian.com/world/2013/apr/24/bangladesh-building-collapse-shops-west> (accessed 18.03.15).

Fig. 3 Schematic diagram of a general vibration control strategy.

Fig. 4 Schematic diagram of a passive vibration control strategy.

For instance, passive vibration control can be modeled as a single-degree-of-freedom system, as shown in Fig. 5, in which this single-degree-of-freedom system is typically obtained from the mechanical vibrations system. On the other hand, this system consists of a rigid mass, which is representing the equipment, and a spring and damper representing the behavior of the isolator. Generally, rubber materials were used as a passive vibration control to reduce the effects of vibration naturally.

Semiactive vibration control is developed to adjust stiffness and damping in real time by applying a control scheme. The adjustment is based on the feedback from the response of the controller where the appropriate command signal is generated to the controller of the system. One of the current examples of an isolator that can change its stiffness or damping based on current or voltage is the magnetorheological (MR) isolator, and the materials used are fluid-based (Sun and Zhang, 2013). Fig. 6 illustrates the mechanism of a semiactive vibration control scheme.

Active vibration control, on the other hand, is the active application of force in an equal and opposite fashion to the force imposed by external vibration. It also works with actuators, sensors, electronic controllers, and signal-conditioning devices. Active control vibration has more advantages compared to passive and semiactive vibration control because it can provide better performance at high frequencies and at the same time reduce the volume and weight of the structure (Yan, 2007). However, this technique requires external energy to drive the active devices continuously. The schematic diagram for this scheme is shown in Fig. 7.

Fig. 8 Two categories of vibration isolator: (a) laminated-rubber bearing isolator and (b) frictional-type sliding isolator.

Recent Development of Vibration Isolators

Examples of vibration isolators can usually be found in buildings. They are used to reduce the risk of damage to structural integrity caused by earthquakes. The recent developments regarding vibration isolators, especially for buildings, including high-rise buildings, and bridges, can be divided into two main categories, which are laminated-rubber bearing and frictional-type sliding isolators, as shown in [Fig. 8](#). The first category is widely used and the second one is still in the early stage of development ([Ibrahim, 2008](#)). These vibration isolators are installed on the foundations of the structures to increase the damping value and to decrease stiffness during strong vibration. However, in this section only the laminated-rubber bearing is discussed in detail, as it relates to the objective of this study. The rubber bearing isolator is often used in base isolation for high-rise buildings because it can maintain the balance of the building ([Lin and Hone, 1993](#)).

A considerable amount of literature has been published on laminated-rubber isolators. The first discussion and analysis of this type of isolator that emerged were presented by [Gueraud *et al.* \(1985\)](#). The study investigated parameters affecting the performance of laminated-rubber isolators in a building located in New Zealand. Two years later, the results of the study were used as a reference for developing a new design of laminated-rubber isolator called resilient-friction-base isolator. This new design then worked in parallel with the previous isolator made from rubber materials, with a steel plate placed around the isolator using Teflon additive. The steel plate was used to maintain the stability of the rubber isolator structure to stop it from bending during strong vibrations. A paper described a comprehensive parametric study conducted on friction coefficient, natural period, damping value, and mass ratio on the resilient-friction-base isolator. Detailed examination of the parameters shows that the isolator can reduce the vibration accelerations and can perform well for lightweight equipment, but the isolator functions do not reach optimal levels if it is used in seismic systems. The isolator also had an ineffective reaction when fixed at the base structure and suffered slippage during strong vibrations. Other researchers have agreed with these findings.

An advanced study of the resilient-friction-base isolator was carried out in 1996 ([Jangid, 1996](#)). Some analysis has been to investigate the relationship between parameter variations on stochastic response in isolated buildings. Coefficient of friction on the resilient-friction-base isolator has been identified as a major contributing factor in the optimum damping of the building structure, and it is effective based on vibration occurrence. However, the above analysis is only valid when the top floor has a minimum root mean square (R.M.S) acceleration. In Japan, the effect of base-isolated structures during seismic activity has been studied ([Aiken, 1997](#)). The new formulation relating the development of base isolator was proposed to predict the seismic response of base-isolated structures. Following this analytical analysis, the mechanical properties of elastomer were identified accordingly into a large strain range. To ensure that the data from the model are trustworthy, a test-rig was developed that was used as a seismic source, and a model of a building was placed on it. A vibration isolator made from rubber was then placed between the building and the test-rig. An accelerometer was used to record all the data during the experiment, and then the obtained data were plotted in a graph where the analytical model data were previously plotted. Based on the study, it has been found that there is a similarity in experimental and analytical data, and, finally, the analytical model has been adopted for future analysis.

In 2004, an elastoplastic damper was proposed to replace the usage of laminated-rubber isolators and resilient-friction-base isolators ([Fujita *et al.*, 2004](#)). This type of vibration isolator has been developed using a spring-mass-damper model where a hysteresis damper was used. In this study, the seismic activity was examined using a hysteresis element and Ramberg–Osgood model. The Ramberg–Osgood model was used to describe the nonlinear relationship between stress and strain, which happen in the damper during seismic excitation. In a two-degree-of-freedom of elastoplastic dampers system, the upper side is used to examine the level of seismic motion, and all data are recorded in amplitude value.

In another major study into vibration isolators, in 1990, Kurihara investigated the effects on the horizontal and vertical stiffness of rubber bearings during large deformations by seismic activity. However, this study focused on nuclear plant buildings located in Japan. The study found that getting the optimum effects for both directions of a rubber bearing is impossible because it does not have a proportional relationship in order to dampen the seismic energy. This finding was validated by applying full-scale rubber bearings and then applying a seismic load of approximately 4900 kN at the bottom. Then, sensors were located at the horizontal and vertical directions of the rubber bearings. According to the experiment, the data showed that large deformations occurred at

Fig. 9 Location of a vibration isolator between building and foundations.

the horizontal direction compared to the other side. In 2007, other researchers also argued about why the above problem occurred (Suy *et al.*, 2007). Several tests have been conducted to validate the previous problem and, finally, it was proposed to combine the rubber bearings with viscous dampers and friction elements on buildings that vibrate due to seismic activities. Mathematical modeling for the combination of these materials was created and it was found that the result is better compared with the previous models developed.

Previously, vibration isolators were placed between the building and foundations because researchers agreed that vibration energy is transferred from the ground to the structure; the application is shown in Fig. 9. However, the first systematic study proposed locating the vibration isolator at the building's roof (Villaverde, 1998; Villaverde and Mosqueda, 1999). A vibration isolator was added between the building's roof and a column that would act as a support for the roof. One of the limitations with this study is that it does not satisfactorily explain by how much the seismic energy will be reduced. Therefore, there are only a few studies to date regarding this matter. The study of the horizontal direction for vibration isolators was continued in 2008. A two-dimensional hysteretic shear-beam type was used to support the vibration isolator during ground motion. This study used statistical analysis to determine several parameters with five different seismic levels. By using a shear-beam, it was found that the level of vibration amplitude transmitted from ground to building was slightly reduced.

Then, study of vibrations in buildings began to not only focus on building structure, but also on the installation of sensitive equipment inside the building, which contributes to the occurrence of vibration and damage. Therefore, in 2005, researchers addressed the damage level probability for sensitive instruments inside a building during vibration (Alhan and Gavin, 2005). It was suggested that these sensitive instruments must have their own mounting system to prevent them being damaged when large vibration energy happened.

Cheng *et al.* (2007) studied rubber bearing tension, focusing on laminated rubber bearing tension in high-rise buildings. The experimental data showed a significant amount of large vibration energy activity where the tension in the laminated rubber bearings did not perform well. Laminated rubber bearings under tension became the main problem if they are used to dampen the vibration occurrence for high-rise buildings during seismic activity. Therefore, a new method was proposed to avoid the possible tension phenomenon occurring. New arrangements for superstructures including column and beam were suggested and joined together with the vibration isolator. This modification was then examined and, finally, the tension behavior of laminated rubber bearings was successfully reduced. In 2009, the study of the low-rise base isolator was used in the previous modification made by Cheng in 2007 (Toopchi-Nezhad *et al.*, 2009). However, the research also employed the unbonded-fiber reinforced elastomeric isolator joint together with existing laminated rubber bearings. By using an analytical model, the result was predicted and the vibration energy from seismic activity was reduced 50 percent compared to previous research by Cheng. A new finding was identified, which is that shear activity took place at laminated rubber bearings when compression load was applied because the nonlinear lateral response behavior of the laminated rubber bearings occurred. Experimental investigations were also conducted in this study, so it can be verified correctly. Based on the experiment conducted, the peak lateral displacement was calculated by using time history analysis, but the result did not have any effect on the building. Finally, the researcher concluded that joining of existing rubber bearings and unbonded-fiber reinforced elastomeric can reduce discomfort inside a low-rise building.

A study of horizontal stiffness of laminated rubber bearings was conducted in 2011 (Du *et al.*, 2011). From the study, it was found that the horizontal stiffness occurred when compressive stress was applied to the structure. The model of a field matrix of a single laminated rubber bearing was derived and then it was connected to the column structure. The relationship

between internal force and isolator displacement was obtained and, finally, the transfer matrix equation was developed using the horizontal stiffness expression. Then, compression stress on horizontal stiffness was examined and the results showed that the inverse proportional relationship for both parties occurred, while the rubber bearing still remained in place, and did not move to another direction. Kobayashi introduced the study of lateral stiffness of laminated rubber bearings (Kobayashi *et al.*, 2012). First, the lateral stiffness was subjected to end rotation and, secondly, the design stress was concentrated at the end of the laminated rubber bearings. Mechanical properties of the laminated rubber bearings subjected to end rotation were evaluated by adopting the mechanical properties of laminated rubber bearings concentrated at the rotational spring. Finally, the degree of fluctuation for both lateral stiffness and bending moment were investigated by using the proposed analytical model, and this model produced some assumptions that need to be taken into consideration, which relate to the location of the isolator at the top of the pile.

An advanced study into the automotive engine isolation system was carried out in 1993 (Singh, 1993). According to the study, the growth of the automotive industry, such as advanced design of the power-train system, engine development, etc., can contribute to the unwanted level of vibration energy on the car body. Therefore, it was suggested that more studies about the automotive vibration isolator for vehicles should be conducted. A study about frequency response on hydraulic engine mounting was carried out by Colgate *et al.* (1995). In the study, nonlinearity behavior such as amplitude reaction on pistons was considered. The researchers believed this behavior could have an effect on vibration amplitude to the driver and passengers when driving. To reduce the effect, research into a new model of engine mount to prevent the large amplitude in automotive engines was carried out (Tiwari *et al.*, 2003) in 2003. Researchers developed a new model and simulated several engine mount designs with different frequency ranges to reduce large amplitude. However, jump phenomenon activity in the engine has also been identified as one of the main factors contributing to the large amplitude activities (Golnaraghi and Nakhaie Jazar, 2001). This problem was identified in 1965 (Timpner, 1965). According to the study, the investigations of nonlinear resonances in large amplitude at high frequencies cannot be predicted by using a simple model. In 1997, the modern engine mounting system was introduced to reduce or eliminate unwanted vibration level to give more comfortable conditions for the driver and passengers when traveling in a vehicle (Brach, 1997), and from this year much research regarding engine mounting began.

The lumped parameter systems model has been used to describe the nonlinearities and hysteretic behavior in hydraulic engine mounting. The lumped parameter systems model is a simplification of the description of the behavior of spatially distributed physical systems into a topology consisting of discrete entities that approximate the behavior of the distributed system under certain assumptions. Several limitations have been listed, especially the boundary condition of the engine mounting between the engine and the car body. A fixed-free boundary condition is chosen where “fixed” represents the condition between engine mounting and car body, while the “free” condition represents the top of the engine. Finite element analysis on hydraulic engine mountings was carried out to investigate the dynamic behavior of the mounting systems (Wenbin and Zhenhua, 2004). It showed that the mounting systems can reduce displacement of the engine from a chamber. A parametric study on hydraulic engine mountings was conducted. This study is very important because, by changing the value of certain parameters, the hydraulic engine mountings can be used to reduce vibration activity from different sources of excitation from an automotive engine. Recent evidence suggests that the value of Young’s modulus and thickness of the isolator can influence the isolator’s potential to reduce the effects of vibration. The first study using viscoelastic materials for engine mounting was conducted by Schmitt (Schmitt and Leingang, 1976). This study proposed using rubber material because its dynamic stiffness performed better at high frequencies due to its damping properties. Therefore, it has become a major factor to design an engine mounting that fulfills many design criteria. This engine mounting was proposed to be installed in the engine, engine cooling system, and car’s body frame because these locations have been identified as having large vibration amplitude, and this was verified by Yu *et al.* (2000). A comparative study between rubber material mounting systems and hydraulic engine mountings was conducted. According to the study, rubber material mounting systems give the ability to reduce large vibration amplitude at low frequency range, and provide better comfort for the driver and passengers in the vehicles. The development of engine mountings has continued to improve the amplitude-dependent properties. The existing rubber material mounting systems are focused on static deflection at low frequency levels, less than 100 Hz. The existing research has proposed the ideal engine mounting system that can be used for static and dynamic deflection at various frequencies. These various frequencies come from engine excitation in several ranges of speed (Peelamedu *et al.*, 2001). The dynamic stiffness for the engine mounting has been investigated to ensure that the system can be used to decrease the vibration levels of engine excitation.

Further study on engine mounting systems was carried out in 2014 (Sun *et al.*, 2014). According to the study, the finite element method was used to solve a problem on isolator stiffness. A two-stage vibration isolation system was used and developed using this method, and the vibration energy was applied at the bottom of the engine to give flexibility to the isolation system. A value of forced vibration was calculated using the finite element model and, based on this value, the quantum of stiffness was optimized. The vibration intensity at vibration isolation was examined and, by using dynamic analysis, it was found that the trend was consistent at the first and second stages of vibration isolation system. Then, the result was validated by using physical testing in the laboratory. From the testing, the trends of vibration intensity for both methods were found to be the same.

Based on the previous discussion of vibration isolators, one conclusion can be made, which is that many studies have been carried out up to now looking at the development of the ideal vibration isolator solutions to ensure that vibration energy can be reduced or eliminated. Hence, it provides stable structures of buildings, car engines, etc., and comfort, especially for environments that people frequent.

Challenges of Rubber Materials as a Vibration Isolator

From previous research (Imbimbo and De Luca, 1998; Manos *et al.*, 2007; Ibrahim, 2008; Bhuiyan *et al.*, 2010; Mishra and Igarashi, 2013; Spizzuoco *et al.*, 2014), researchers agree that rubber is a versatile and adaptable material. This material has been used successfully in many engineering applications such as in mechanical engineering problems, civil construction, automotive parts, aeronautical solutions, and many more, and the material is still sustainable and being used today. The rubber elastomer acts like a spring. Therefore, it can also be used as a component for a mounting system to reduce unwanted vibration amplitude in many fields. It also has a large strain capability and it can store more elastic energy per unit volume. Many studies have been conducted that demonstrate that this material is very safe and it is much better than steel material if produced properly (Ibrahim, 2008).

Static and Dynamic Behavior of Rubber Materials

This material has some inherent damping, which is very useful in springs, and so it can be used to counter resonance behavior when the frequency range of the material is the same as the environmental frequency (Yin *et al.*, 2010). Essentially, rubber can be bound together with other material such as metal, steel, aluminum, and others by using chemical additives. On the other hand, it implies that rubber can give more stiffness value to the other materials in shear and compression phenomena. The installation process of rubber is very simple and only takes a short time compared to other materials. Rubber requires less maintenance, and its elasticity and durability can be sustained for many years after the installation process.

Essentially, rubber has a high polymer content, and the chemical bonding acts as a smoothing agent that feels as smooth as silk, cellulose, and proteins (Mitra *et al.*, 2010). The bonding also has the same characteristic as in petroleum products, which are plastics, resins and synthetic rubbers. In chemical behavior, rubber has a very long molecule, which results in the creation of a durable repeating monomer. With this repeating monomer, rubber can be contoured and is flexible for working in an extreme ambient and very high temperature. At a high temperature, the rubber shape is deformed, but it will return to its original shape when the temperature goes down. The rubber is basically created by a hydrocarbon through an empirical rule (Dasgupta *et al.*, 2007). This hydrocarbon bonding is called a monomer, and is also known as isoprene. The rubber latex can easily be found in Malaysia. Rubber trees are tapped every day and the rubber milk is called latex. After the coagulation process, which takes some time, the crumbing process takes place and finally it is transformed to Standard Malaysian Rubber (SMR). The grade of SMR is dependent on the technical specifications, applications, mechanical properties, and resistance to environmental conditions.

To create the rubber that can be used in engineering applications, vulcanization or curing process is applied and some chemical materials are joined together to produce a chemical response, and this reaction is called vulcanization. The basic vulcanization process was established in 1839 and it was discovered by Charles Goodyear (Shelton, 1983; Raue *et al.*, 2014). Sulfur is used in this procedure to add durability and elasticity and reduce the sensitive behavior of the rubber due to temperature range (Yuan, 2010). Additionally, sulfur also gives a bonding effect inside the rubber molecule and at the same time the original length of the rubber molecule becomes shortened. When the rubber molecules become shortened by sulfur, it makes natural rubber more resistant to wear and tear when applied at high temperatures (Yuan, 2010).

In engineering applications, most rubber products are supplied with filler. This filler generally comes from carbon black, which must be 33 percent of the total weight before the vulcanization process starts. Basically, carbon black is divided into three categories: reinforcing, nonreinforcing, and semireinforcing behavior. In the reinforcing category, it is also called abrasion grade blacks (NR Technical Bulletin, 1992; Yuan, 2010). It can improve the tear and abrasion properties, and at the same time rubber in this category can increase the modulus, creep, and hysteresis behavior. On the other hand, rubber in the nonreinforcing category, also known as thermal blacks, has less effect on the behavior described in the previous discussion. Furthermore, the nonreinforcing type has moderate modulus, creep, and hysteresis effects. Lastly, the semireinforcing type gives additional effects to the other two categories, which are tensile strength, abrasion resistance, and chemical adsorption. Many researchers agree that rubber has unique behavior compared to other engineering materials. Firstly, the shear and Young's modulus value of rubber are very low and it is many times smaller than the bulk modulus value of the materials. Secondly, rubber is like other materials in that it can be deformed elastically, but the difference is that it can be stretched hundreds of times and never fail, and the shape will return to the original shape. The mechanical property of filled rubber is shown in Table 1 and, from this table, it was compared with three other materials. The table is very important in order to know the specification of rubber itself and also gives more information about its hardness, tensile strength, elongation, stress, and many more features. These data are adopted from the literature and have been verified by the Malaysian Rubber Board (NR Technical Bulletin, 1992).

Theoretically, the bulk modulus of rubber is around 2000 to 3000 MPa and this value is a thousand times larger than the value of the shear modulus. Agreeing with this value, one conclusion that can be drawn is that this material is hardly altered in volume when the deformation phenomenon occurs. When rubber changes shape, its stiffness value become much larger; in short, it becomes like a compressible spring. Moreover, Poisson's ratio for rubber is 0.5, which means that the material has little resistance for a small stream when a force is applied (NR Technical Bulletin, 1992; Boiko *et al.*, 2008). All of the discussion shows that this material has incompressibility behavior that makes it more durable and long lasting with less maintenance required, and not easily prone to wear and tear.

It is also important to have an in-depth knowledge of the stress-strain behavior of rubber. In an unfilled condition, rubber can be deformed in tension and compression. This deformation happens approximately in linear strains up to a certain percentage

Table 1 Comparison of a soft gum rubber, filled rubber, mild steel, and water

Property	Gum rubber ^a	Filled rubber ^b	Mild steel	Water
Hardness (IRHD) ^c	43	65	100	0
Tensile strength (MPa)	26	22	460	–

from the total length. Here, Young's modulus will play a role, which will take place on low strain regions (NR Technical Bulletin, 1992; Liao et al., 2011). On the other hand, a filled condition makes rubber gain more stiffness in value but in nonlinear strains. Thus, the rubber can be deformed in tension or shear even if the strain is less than one percent.

Hardness has been considered as one of the contributing factors for the mechanical behavior of rubber. The elastic deformations are measured under a specified load by using the Shore Durometer A. Rubber is totally different compared to metal materials, especially in hardness behavior, and, because of that, its irreversible behavior can be measured like that of other metals (Peters et al., 2009). International Rubber Hardness Degrees (IRHD) were verified in the 1980s. Hardness is relatively simple and easy to obtain but is subject to an uncertainty of about ± 2 degrees (Lee et al., 2014). The testing is carried out with 20 MPa force, where only a small region near the surface is used for the test because it is enough to represent the results for all of the material.

When applying forces to rubber, it is important to look at and discuss energy dissipation. Hysteresis occurrence is the correct term to be discussed because through this the energy dissipation occurring in the rubber will be better seen (Niemczura and Ravi-Chandar, 2011; Cao et al., 2014). According to the definition of hysteresis, it means the area between a loading and unloading curve in a load-deformation cycle (Ibrahim, 2008). Hysteresis occurs in all rubber types. It happens because rubber material is resilient and this means that, when any force or energy is applied to it, it reacts by returning to its original form. Nevertheless, this process depends on the distance of the polymer molecules, filling used, and also the compounding materials. For instance, when force is applied to rubber without filler, the hysteresis behavior is really trivial but when a force is applied to rubber with filler the behavior changes. When hysteresis increases, the rubber is suitable to be used instead of other materials in extensible applications; this is due to fear of crystallization occurring if other materials are used (NR Technical Bulletin, 1992). By applying higher heat, hysteresis also happens in this rubber material. The deformations will be repeated and, finally, the root point of the repeating area will be shifted. When low temperature is applied, hysteresis does not occur because the rubber becomes a thermal conductivity material. Also, with low hysteresis, rubber is suitable to be used as an isolator or a vibration absorber to block and break up the vibration energy. It can also produce more damping without any compromise and it also reduces the loss angle.

Rubber is not perfectly elastic and many researchers have showed this, and they also conclude that this material possesses a unique form, which is that the value is always less than the strain point of accumulation, but it is still better than other materials. Sinusoidal deformation takes place when the relationship between force and deformation is linear and also in the same frequency range. Modulus is one of the properties that contribute to the dynamic behavior of rubber. This is because, when the dynamic modulus of filled rubbers decreases in amplitude range, at the same time the strain applied is increased (Tsai and Hsueh, 2001). Essentially, the vulcanization process can be performed on this material with temperatures as low as 5°C and frequencies not exceeding 1000 Hz (NR Technical Bulletin, 1992; Yuan, 2010). For unfilled rubber, this process sees a minimum change over the shear modulus and it usually does not increase by more than 25% of the original value. The shear modulus of the material will experience dramatic changes if natural rubber is used in this process where the temperature and frequency are the same. When the frequency increases above 1000 Hz, the modulus will be directly proportional to the value of the earlier frequency. If the frequency increases, this implies that the modulus increases too. Rubber also will become as hard as glass when the vulcanization process is

performed at an ambient temperature. This often occurs when the temperature used is below 5°C and below the frequency of 1000 Hz. At this stage, the modulus will vary in its behavior due to it being a difficult process, and recording the actual modulus will become more complex.

Dynamic modulus for rubber will only happen on the filled type, and will occur if the amplitude of strains is increased. Some effects will occur that will cause a slow interaction between the filler and the rubber matrix. This will result in changes to the value of the static modulus where the value of strain will increase, and also change the quantum of magnitude. In theory, this will reduce the modulus and at the same time the strain value will increase.

Loss angle is employed to measure the damping value and the hysteresis value for rubber (Suzuki and Nishimura, 2010; Karabork, 2011). Both of these values are based on the cyclic deformation cycle. For unfilled types, during the vulcanization process at ambient temperatures and frequencies not exceeding 1000 Hz, the loss angle is too small. The loss angle is estimated to be around 4 degrees and only occurs at the lowest frequency of 60 Hz. Thus, the damping is more sensible to look at rather than the modulus, and, the damping is increased if the frequency increases, but at the same time bringing down the temperature value. At frequencies above 1000 Hz, regardless of whether the rubber is unfilled or filled, the vulcanization process will increase the damping value, even when the temperature is 20°C. A loss angle of 10 degrees only happens when the frequency reaches 2000 Hz. The value of the loss angle, which is recorded at high frequencies, is useful for designing isolator systems for engineering applications. The difference is significant if the comparison value for the loss angle between unfilled and filled types of rubber is conducted correctly. After the vulcanization process, the loss angle for the filled type has a high value compared to the loss angle of the unfilled type.

Effects of Spring Behavior in Rubber Materials

Most researchers agree that the nature of rubber is equal to the nature of a spring (NR Technical Bulletin, 1992; Ibrahim, 2008). Hence, it can be said that rubber can replace springs. In addition, rubber is the only material that can react like a spring. This is because rubber has a number of characteristics that are not available to other materials. One of the most important characteristics of rubber is the resistance to fatigue. This is because, if a tension force is imposed, rubber can overcome it and, finally, when the force is removed, the rubber will return to its original shape. Rubber also has high resilience because it can accommodate a large number of forces that are applied to it by small mechanical changes (NR Technical Bulletin, 1992; Ibrahim, 2008). Additionally, it also generates a very low heat when it flexes. Other than that, rubber also has a higher degree of strength, which makes it the most suitable material to be used under huge dynamic load. It also has low compression behavior, stress relaxation (which means it can be observed to decrease in stress in response to the same amount of strain generated in the structure), and a low damping ratio. All of the criteria mentioned above mean that rubber is suitable to be used as a spring. Nevertheless, it can also be used as bearings, isolators, mountings, tires, and for other industrial purposes.

From the description above, a number of differences between the use of rubber springs and metal ones have been identified, and some conclusions can be made. First, if using a rubber spring, unnecessary maintenance can be eliminated because of the nature of rubber itself. In addition, springs made from rubber can store a lot of energy and therefore these springs are able to withstand heavier loads than springs made of metal. Springs made from rubber are easier to optimize because the stiffness can be varied by simply changing the formula of the compound. Therefore, rubber springs are more widely used than other types. Rubber springs are also easy to install compared to other materials. A misalignment does not exist in this material too, therefore it can be used for a long time. This material also has high resilience; thus, it is more suitable to be used in places where there is high risk to exposure and to resonant vibrations.

Apart from the above discussion, it is also very important to discuss the natural frequency of rubber, because this will determine the dynamic stiffness of the material. Dynamic stiffness is used to control static deflection that happens on a body mounting system (Ibrahim, 2008). When a system is supported by a spring made from rubber, vertical natural frequency can be determined using the formulation given by

$$f_n = \frac{16}{x_y} \quad (1)$$

where x_y is the static deflection of the spring (Ibrahim, 2008).

Other than that, most of the engineering applications that use rubber as a mounting system emphasize the transmission of vibration energy to a structure (Burdzik, 2014; Brennan *et al.*, 2014). Thus, scientists and engineers have been using rubber as a vibration isolation system and it is believed to be used optimally and can prevent vibration energy from reaching the structure, as mentioned above, although it occurs at low frequency (Ibrahim, 2008).

Transmissibility, T_r , method is used to determine the ratio of vibrational energy generated before and after using the vibration isolation system. In addition, this method can also be used to divide the forces that have entered a structure with the force imposed on the structure, respectively. This transmissibility is expressed in terms of ratio between distributing frequency, f , to the natural frequency, f_n , resulting from the vibration isolation system.

Effects of Metal Plates Inside Rubber Materials

Currently, most rubber materials are used as springs because of the nature of the materials themselves (Chang, 2002; Banerjee, 2004). To maintain the natural properties of a spring, rubber should be used together with other materials, and currently the most

Fig. 10 Rubber materials bonded with a metal plate.

popular material in use with rubber is a metal plate. The main purpose is to tighten the grip and also the bonding property of natural rubber acts to connect it with the other material. In addition, the metal plate is applied to raise the vertical stiffness of a bearing or spring system, respectively. When a metal plate is utilized in conjunction with rubber, the bonding agent for both materials needs to ensure the rubber does not slip when force is applied. **Fig. 10** shows the arrangement of rubber materials with a metal plate.

Two criteria are important to consider in providing a strong bond between rubber and a metal plate: the strain concentration and friction (Nikiforova and Sheryshev, 2012). The strain concentration is used as a main factor to ensure the alliance between the two materials can be managed easily. If this factor is ignored, most likely the bonding will be damaged and the result will be an improper function or total failure. Errors that often occur are because many researchers only focus on the environment and condition in the middle between the rubber and the metal plate. But, the fact is those areas are not at high risk as there is a strong bonding condition. The main area for concentration of this strain should be focused on the corners or edges of the material itself. This is because most bonds that involve two or more different materials do not have a strong bonding in this area. The reason is that the surface area is too small and eventually the area becomes at risk of function failure. Friction is seen as the second-most important factor in this section. Very high-friction material will not slip when force is applied to the surface. Therefore, a sandblasting process should be performed on the metal plate so that the surface becomes rougher and provides greater grip. To ensure that the friction increases, the additives are used to make the bond stronger between rubber materials and metal plate (Tarhini and Hamade, 2012).

Transmissibility of Rubber Materials as Vibration Isolators

Vibration Isolators Performance

Currently, there are over 3500 articles – conference papers, journals, magazines, books, etc. – that discuss the role of vibration isolators in dissipating vibration energy (Nelson, 1994; Macinante, 1984). All of these articles have discussed the use of vibration isolators in many fields such as instrumentation, civil structure, mechanical systems, automotive, aeronautic application, aerospace vehicle, and earthquakes. There is a method to determine the performance of vibration isolators, which is called transmissibility.

It is very beneficial to assume that the base structure of a system is rigid, as it can give more simplicity in determining the transmissibility and, finally, it is easy to solve. But, if the base structure is not rigid, the transmissibility equation becomes more complex and difficult to solve. Available literature indicates that there are many different methods that can be used to solve the vibration isolator problem; however, all the methods are based on the approximation solutions, which use the differential equation formulation. The finite element method is also used to determine the solution for vibration isolators.

Previously, it has been shown that using a rigid base structure gives more advantages when solving a problem regarding vibration isolators. However, not all systems have a rigid base structure, as Blackwood and Nelson proved in 1993 and 1994, particularly. According to these two researchers, a flexible base structure will lower the vibration isolators' performance and make them less effective in reducing or blocking vibration energy transmitted by the isolator itself. Both researchers have suggested that base structure design is an important issue to consider in order to ensure that vibration isolators provide the maximum performance during vibration.

In 2007, Yan developed an approximation technique to determine the transmissibility of a flexible base structure. This technique uses a closed-form solution of distributed parameter system by associating it with a state-space technique, although it is very complex to solve the problem. The formulation is valid for self-joint and non-self-joint systems, and the boundary conditions must be nonhomogeneous with each other. After 2 years, Yan improved the formulation that determined the solution for complex problems generated by the distributed parameter systems. The new formulation can solve many complex problems that occur on the beam, plate, rod, point, and rigid bodies. The novelty is that the formulation does not involve any approximation

technique to solve the problem. An exact value is used to determine the eigenvalues and eigenfunctions for the flexible base structure. This new formulation is still used by researchers today.

Massless Isolators

Consider a machine with internal force, f_e supported with an elastic rubber, as shown in Fig. 11.

By assuming the machine vibrates only in the vertical direction with displacement at y , a simple model of the system can be assumed to consist of a mass, a spring, and a damper, as shown in Fig. 12, where the elastic mounting from the rubber has the property of stiffness and damping. The equation of motion for the single-degree-of-freedom system for this system can be expressed as

$$m\ddot{y} + c\dot{y} + ky = f_e(t) \quad (2)$$

where m is the mass of the motor, c and k are the damping and stiffness constant, respectively, and where $\dot{y} = dy/dt$ and $\ddot{y} = d^2y/dt^2$ (Salim *et al.*, 2014).

For harmonic motion at frequency ω where $f_e = F_e e^{i\omega t}$ and thus $y = Y e^{i\omega t}$, where F_e and Y are the complex amplitudes of the force and displacement, respectively, Eq. (2) becomes

$$(-\omega^2 m + i\omega c + k)Y = F_e \quad (3)$$

The injected force f_i to the base structure through the contact point of the mounting (spring and damper) can be represented by the free body diagram as shown in Fig. 13.

From Fig. 13, the equation of motion for the transmitted force f_t is given by

$$f_t = ky + c\dot{y} \quad (4)$$

Fig. 11 Motor with supported elastic rubber mount.

Fig. 12 Single-degree-of-freedom system for a massless isolator.

Fig. 13 Free body diagram for transmitted force for the single-degree-of-freedom system.

where, for harmonic motion, Eq. (4) thus becomes

$$F_t = (k + i\omega c)Y \quad (5)$$

From Eqs. (3) and (5), the transmissibility force, T_F between transmitted force, F_t and excitation force, F_e can be therefore expressed as

$$T_F = \left| \frac{F_t}{F_e} \right| = \left| \frac{k + i\omega c}{k - \omega^2 m + i\omega c} \right| \quad (6)$$

Eq. (6) can be written in terms of the natural frequency, ω_n and the damping loss factor ξ given by

$$T_F = \sqrt{\frac{1 + 4\xi^2(\omega/\omega_n)^2}{\left(1 - \frac{\omega^2}{\omega_n^2}\right)^2 + 4\xi^2\left(\frac{\omega}{\omega_n}\right)^2}} \quad (7)$$

where, $\xi = c/2\omega_n m$ and $\omega_n = \sqrt{k/m}$.

From Eq. (7) where the excitation frequency is much lower than the natural frequency of the system ($\omega \ll \omega_n$) yields

$$T_F \approx 1 \quad (8)$$

This is where the injected force is fully transmitted to the base. At resonance where $\omega = \omega_n$, Eq. (7) becomes

$$T_F = \frac{1}{2\xi} \quad (9)$$

where, the transmissibility is only controlled by the damping.

For the excitation frequency well above the natural frequency ($\omega \gg \omega_n$), Eq. (7) gives

$$T_F = \frac{2\xi\omega_n}{\omega} < 1 \quad (10)$$

where, the transmissibility can be further reduced as the frequency increases.

The transmissibility from Eq. (7) is plotted in Fig. 14 in terms of the normalized frequency, ω/ω_n . It shows that there is only one resonant peak and it represents the system resonance from the mass of the machine and the stiffness of the mounting. The frequency range below $1.4 \omega_n$ shows the transmitted force equal to or greater than the excitation force (amplification region) as indicated by Eqs. (8) and (9). Above $1.4 \omega_n$, the transmitted force becomes smaller than the excitation force. This is the frequency range where the mounting acts as the isolator. This transition frequency of $1.4 \omega_n$ can be shown as follows.

From Eq. (7) where $T_F < 1$ and assuming small damping ($\xi \ll 1$), this gives

$$\sqrt{\frac{1}{\left(1 - \frac{\omega^2}{\omega_n^2}\right)^2}} < 1 \quad (11)$$

As shown in Fig. 14, at the area of the isolator where $\omega > \omega_n$, thus Eq. (11) must be written as

$$\frac{1}{\frac{\omega^2}{\omega_n^2} - 1} < 1 \quad (12)$$

Finally, Eq. (12) yields

$$\omega > \sqrt{2}\omega_n \quad (13)$$

Fig. 15 shows the results of transmissibility for the increasing damping values. From Eq. (10), the damping is inversely proportional in the isolation region. By increasing the value of the damping, the transmissibility increases at the isolation region although the peak at resonance can be reduced. This is a “trade-off” situation for a machine system to have a low amplitude in the

Fig. 14 Performance of the single-degree-of-freedom for a massless isolator.

Fig. 15 Transmissibility of the single-degree-of-freedom for a mass isolator when increasing the damping value: - $\xi=0.02$; - - $\xi=0.04$; · · $\xi=0.06$.

case of resonance, but the isolation performance has to be sacrificed. Low amplitude at resonance is important, for example, during the machine start up where the machine will pass through the resonant frequency before finally reaching the steady-state speed.

Two-Degree-of-Freedom System of Massless Isolator

Considering the rigid foundation of the machine is located on another soft foundation having stiffness k_2 , and damping c_2 , as shown in Fig. 16.

The equation of motion can be derived as

$$f_e(t) = m_1 \ddot{y}_1 + c_1 (\dot{y}_1 - \dot{y}_2) + k_1 (y_1 - y_2) \quad (14)$$

$$0 = m_2 \ddot{y}_2 + c_1 (\dot{y}_2 - \dot{y}_1) + c_2 \dot{y}_2 + k_1 (y_2 - y_1) + k_2 y_2 \quad (15)$$

Fig. 16 Motor with two supported elastic rubber mounts.

Fig. 17 Two-degree-of-freedom system.

and

$$f_t(t) = c_2 \dot{y}_2 + k_2 y_2 \quad (16)$$

where, m_1 is the mass of the motor, m_2 is the mass of the rigid foundation, c_1 and k_1 are the damping constant and stiffness constant of the rubber mount under the motor, and c_2 and k_2 are the damping constant and stiffness constant of the rubber mount under the rigid foundation.

The foundation can now move relative to the motion of the machine, say with displacement, $y_2(t)$, and the system which can now be modeled as the two-degree-of-freedom system, as shown in Fig. 17.

Following the derivation as in the single-degree-of-freedom system, Eqs. (14) until (16) can be written as

$$F_e = -\omega^2 m_1 Y_1 + j\omega c_1 (Y_1 - Y_2) + k_1 (Y_1 - Y_2) \quad (17)$$

$$0 = -\omega^2 m_2 Y_2 + j\omega c_1 (Y_2 - Y_1) + j\omega c_2 Y_2 + k_1 (Y_2 - Y_1) + k_2 Y_2 \quad (18)$$

and

$$F_t = j\omega c_2 Y_2 + k_2 Y_2 \quad (19)$$

Fig. 18 Transmissibility of the two-degree-of-freedom system when increasing the damping value: - $\xi=0.02$; --- $\xi=0.04$; ... $\xi=0.06$.

Eq. (18) yields the relation between displacement of the motor and that of the foundation as

$$Y_1 = \left[\frac{-\omega^2 m_2 + j\omega(c_1 + c_2) + (k_1 + k_2)}{j\omega c_1 + k_1} \right] Y_2 \quad (20)$$

By substituting Eq. (20) for Eq. (17), the excitation force can be expressed by

$$\begin{aligned} F_e = & -\omega^2 m_1 \left[\frac{-\omega^2 m_2 + j\omega(c_1 + c_2) + (k_1 + k_2)}{j\omega c_1 + k_1} \right] Y_2 \\ & + \left[j\omega c_1 \left[\frac{-\omega^2 m_2 + j\omega(c_1 + c_2) + (k_1 + k_2)}{j\omega c_1 + k_1} \right] Y_2 - Y_2 \right] \\ & + \left[k_1 \left[\frac{-\omega^2 m_2 + j\omega(c_1 + c_2) + (k_1 + k_2)}{j\omega c_1 + k_1} \right] Y_2 - Y_2 \right] \end{aligned} \quad (21)$$

Using Eqs. (19) and (21), the transmissibility $T_F = |F_i/F_e|$ can be calculated.

The transmissibility results for the two-degree-of-freedom system are shown in Fig. 18 together with those for the single-degree-of-freedom normalized with respect to the fundamental natural frequency. The two peaks represent the first and the second natural frequencies of the system; each has a unique vibration behavior (mode shape). It can be seen that, apart from the existence of the second resonance, which degrades the oscillator performance of the original single-degree-of-freedom system around that frequency, the transmissibility is greatly improved above the resonant frequency. The second peak can be reduced by increasing the damping of the mount of the rigid foundation. However, as the damping is increased, the transmissibility above the second resonance frequency degrades approaching the transmissibility of the single-degree-of-freedom system.

Conclusion

The recent advances and challenges of rubber materials as a vibration isolator have been covered in this article. In conventional vibration isolation theory, vibration isolators consider several parameter elements, which are elastic springs and viscous damper, which is named as lumped parameter system in this article. Most of the previous study had developed the model of vibration isolators by presuming it to be a massless isolator. This simplification basically can be used at low frequencies, in which the wavelength of the vibration isolators is long enough compared to the exact dimension of the isolators. Thus, to model vibration isolators that can work in higher frequencies, the consideration of the distributed mass, stiffness, and damping are important; however, this is not covered in this article. In addition, this topic also represented the massless isolator with different number of degree-of-freedom. Overall, by increasing the number of degree-of-freedom, a new natural frequency is presented, and finally the transmissibility improved more than 30 percent above the previous frequency.

The Circular Economy: Additive Manufacturing and Impacts for Materials Processing

Lorna Fitzsimons, Greg McNamara, Muhannad Obeidi, and Dermot Brabazon, Dublin City University, Dublin, Ireland

Introduction

The move to a circular economy (CE) has been identified as an important and necessary shift in the way we do business and conduct our lives, locally and globally. Its potential impacts are manifold and wide ranging, leading to expected significant societal, environmental, and economic benefits. Primarily, the CE concept aims to decouple natural resource consumption from economic growth and activity. According to the Ellen MacArthur Foundation, this involves three key aspects: Designing out waste and pollution; keeping materials and products in use; and the regeneration of natural systems ([Ellen MacArthur Foundation](#)). The EU has implemented the ambitious 2018 action plan for the European transition towards a CE, again with several themes and target areas common to the Ellen MacArthur foundation: Maintaining and prolonging the value of products within the economy; ensuring a low carbon economy; and promoting efficiency and minimizing waste (EU). In the literature, however, the definition of the CE is not consistent and means different things to different stakeholders, with key principles of the CE approach often being selectively omitted, according to the interests of the definer. [Kirchherr et al. \(2017\)](#) analyzed 114 definitions of the CE concept in an effort to determine the current understanding of the CE concept among practitioners and scholars. Conceptual ambiguity, whether intentional or not, is a significant challenge for the implementation of the CE concept as the fundamental message can lose its potency, and in general become part of Engelman's language of "sustainable" ([Engelman, 2013](#)).

Notwithstanding the conceptual CE differences in the literature, there is an urgent need to reimagine how we utilize and manage our natural capital. Historically the capitalist economic model has often neglected the economic cost of natural resources ([Georgescu-Roegen, 1971](#)) and overlooked the vital contribution of the natural environment to economics ([Lovins, 2005](#); [Lovins et al., 1999](#)), and society in general. The capitalist economic model can be defined as linear: Primary resources are extracted from finite deposits in the natural environment and undergo preliminary processing; these resources are subsequently used as raw material inputs for manufacturing activities in conjunction with other inputs such as energy, water, and labor to transform the raw materials into consumer products. Note that these other inputs also require treatment/processing. The generated products are used by consumers and discarded after finite time periods, which vary according to the product type and life-cycle. It is important to recognize that each aforementioned stage involves various levels of waste generation and further associated resource utilization. The waste generated must be managed and mitigated to ensure that it too does not pose a further environmental threat, and the pattern continues. It is clear that this linear extract–use–dispose cycle is not sustainable with regard to either the extraction and subsequent depletion of natural resources or the generation and disposal of waste streams and pollution. Recent efforts have focused on developing a more sustainable economic model, with 4 "R" strategies such as Reduce, Reuse, Recycle, and Recover becoming more prevalent, and being recently superseded by the more nuanced nine "R" framework; see [Fig. 1](#) (10 strategies in fact).

The CE not only considers sustainability from an environmental perspective but seeks to embed it in our economic models and thinking. In principle, the concept of the CE and its implementation requires an integrated, interdisciplinary, and holistic approach spanning engineering and science, economics, policy and regulation, the broader humanities disciplines, and perhaps most importantly human behavioral changes.

Researchers have considered the CE approach and its impact on various manufacturing sectors. [Barrett et al. \(2018\)](#) reviewed the CE approach *inter alia* as a means to mitigate emissions and decarbonize the industrial sectors in the UK. They also considered methodologies such as exergy analysis and life cycle assessment (LCA). [Lieder and Rashid \(2016\)](#) reviewed CE implementation in the context of the manufacturing industry. [Winans et al. \(2017\)](#) considered the evolution of the CE concept and reviewed current applications of the CE concept across 20 countries, including the intersection between the CE and other thematic areas, for example, policy instruments, technological social and organizational innovation, and material flows and value chains.

The main objective of this article is to consider the CE approach in light of advanced, additive manufacturing and to assess any potential benefits with respect to traditional manufacturing processes. Furthermore, the CE approach will be compared with other engineering approaches to assess environmental impact, improve efficiency, and reduce waste.

Methodologies

Several methodologies are used to determine the environmental impact of production processes and production systems and to improve system efficiency, both economically and thermodynamically: Exergy analysis; thermoeconomics, which links thermodynamics and economics; LCA; and life cycle cost assessment (LCC).

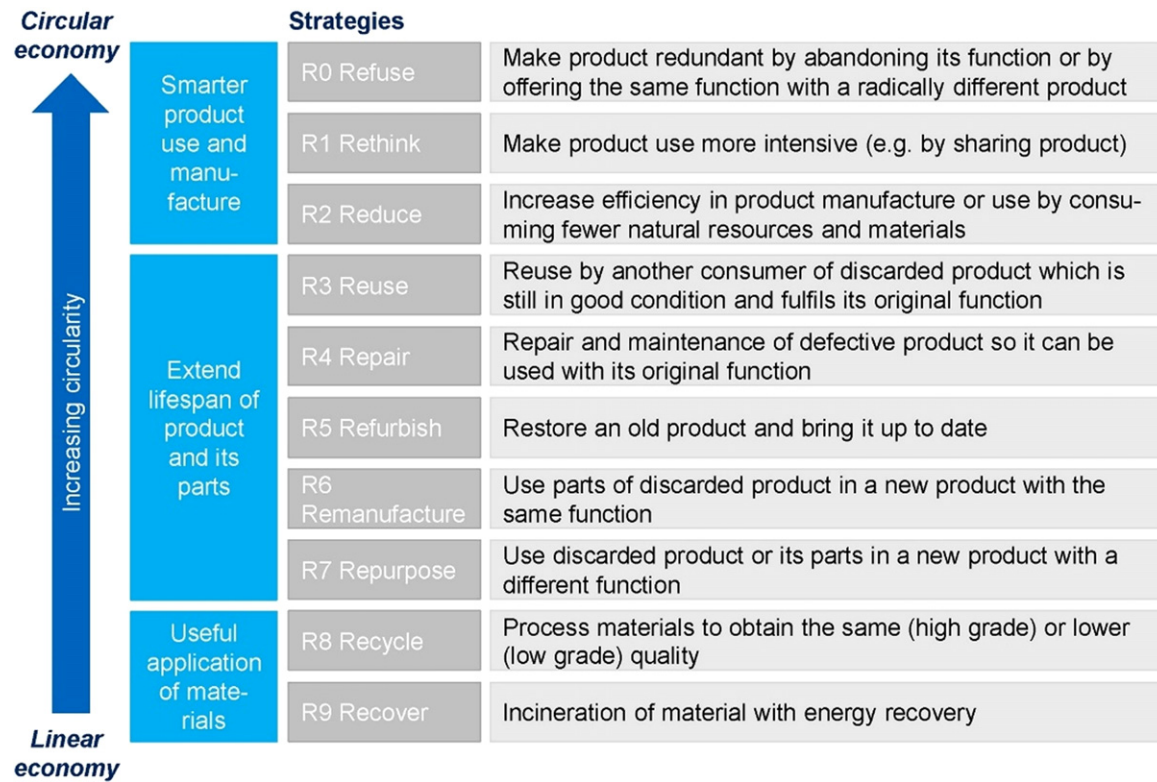

Fig. 1 The 9R framework. Adapted from Potting, J., Hekkert, H., Worrell, E., 2018. Circular Economy: Measuring Innovation in “The Product Chain”. The Netherlands: PBL Netherlands Environmental Assessment Agency. Kirchherr, J., Reike, D., Hekkert, M., 2017. Conceptualizing the circular economy: An analysis of 114 definitions. *Resources, Conservation and Recycling* 127, 221–232.

Exergy Analysis

Exergy analysis is widely used and accepted by many leading energy experts as providing a powerful basis for the characterization and optimization of thermal or energy systems. Incorporating both the first and second laws of thermodynamics, exergy analysis considers the quality and the quantity of energy in systems.

Exergy, a thermodynamic property, is a theoretical measure of the available (or potential) work a system can do as it comes into equilibrium with its environment. As a corollary, therefore, it is also a theoretical measure of the necessary work input to bring a system from its relevant reference environment to a desired thermodynamic state. The exergy at any point in a system is measured with reference to the “dead state,” that is, the state of the environment. Common forms of exergy include kinetic exergy, potential exergy, thermomechanical exergy, and chemical exergy. When equilibrium between the system and the environment is reached, the opportunity to do useful work no longer exists and the value of exergy is zero.

Thermodynamic irreversibilities are quantified by carrying out an exergy analysis, which consists of several stages:

- The exergy of process streams and systems is evaluated (mechanical, thermal, and chemical exergy with reference to the dead state);
- The rate of exergy destruction is determined using an exergy balance;
- The exergy balance and exergy destruction rates are used to calculate the exergetic efficiency of system components or overall system efficiency.

Although the rate of exergy destruction, initially, may not be significant as a stand-alone quantity, it does provide a critical benchmarking tool, both for the components within a multicomponent system and between similar systems. The rate of exergy destruction is also an ideal platform for assessing possible system improvements and optimization.

Life Cycle Cost Analysis, Life Cycle Assessment, and the Circular Economy

Manufacturing processes were reported to account for 19% of global greenhouse gas (GHG) emissions in 2010 (Díaz *et al.*, 2012). With global population growth predicted to exceed 8 billion by 2025 (Vörösmarty *et al.*, 2000), it is reasonable to assume that manufacturing-related GHG emissions and associated resource consumption will experience a relative increase in the coming years, particularly in developing regions such as Africa, Asia, and South America where the rate of industrial expansion is currently

twice that of the established industrial powerhouses (Maddison, 2007). It is important, therefore, that industry continues to develop sustainable manufacturing practices, improve energy efficiency, and reduce nonrenewable resource consumption, while at the same time maintaining economic viability. The challenges associated with achieving this *ideal* business model are varied and too numerous to explore in any great depth in this article. However, one area of particular importance is how to adequately measure or predict the efficacy of planned improvement actions, or novel technology implementation.

Life cycle cost analysis (LCCA) and LCA are terms often used interchangeably to describe analytical tools used for decision support. Both methods of analysis may be similar in objective, and to some degree scope, but can differ distinctly in their methodology, results, and sometimes in their final recommendations. Actions that might seem favorable on a company's balance sheet may not always align perfectly with a positive environmental profile. LCCA refers to a procedure in which the total *financial* cost of ownership of a product or system is evaluated over its entire economic life time. Historically, investment decisions would weigh heavily on initial capital expenditure (CAPEX). But in 1965 a report entitled *Life Cycle Costing in Equipment Procurement* (Logistics Management Institute LMI, 1965) prepared for the U.S. Department of Defence, it was determined that the cost of system acquisition may be small in relation to the cost of ownership (Eisenberger and Lorden, 1977). Dhillon (2009) reported that the cost of system ownership could range from 10 to 100 times the cost of acquisition. The LCCA concept introduced transparency to costing, and exposed hidden costs that were not immediately apparent with traditional costing methods. In his review of the LCC technique Harvey (1976) described the LCC of an item as "...the sum of all funds expended in support of the item from its conception and fabrication through its operation to the end of its useful life." The LCCA approach makes it possible to determine the most cost effective solution amongst a range of alternatives by considering all cash flows over the lifetime of the system, and allows practitioners to identify potential trade-offs between initial capital investment costs and long-term cost savings.

LCA is a holistic analysis tool used to assess or measure the environmental impact associated with a product or service. The main advantage of LCA is the scope or range within which it operates. Unlike other environmental assessment tools such as environmental impact assessment (EIA), ecological footprint, environmental risk assessment, or cumulative energy demand, which tend to focus on the immediate local environmental risk or impact, LCA considers all of the upstream and downstream processes associated with the production of goods or services throughout its entire life cycle. Indeed, in many cases the most significant source of environmental impact can occur far away from the point of production, use of goods, or provision of services, for example, the production of energy used in manufacturing processes is often the largest contributor to a product's environmental profile. The term "cradle to grave" is often used to describe the LCA process, which begins its resource use and emissions accounting from the acquisition of raw materials from the earth's natural resources, right through to the disposal or recycling of material at the end of the product or service life time (Fig. 2).

The LCA methodology, now an established framework set out in a series of ISO standards (ISO, 1997, 1998, 2000), allows practitioners to identify "hotspots" throughout a system and take appropriate actions for improvements in waste management, recycling, and energy use. This method of EIA has been practiced in one form or another since the late 1960s (Hunt and Franklin, 1996). However, in more recent times, the concept of a *cradle to cradle* (C2C), *closed loop*, or CE is considered by some to be the current gold standard in sustainability solutions.

At a European Union level the advocacy of the CE concept could be viewed as the latest in a series of measures taken by the European Commission (EC) to address the issues of economic and environmental waste management, resource-use efficiency, and consequently contribution to the reduction of European GHG emissions. In 2005 the EC published its report *Thematic Strategy on the Prevention and Recycling of Waste* (EU Commission, 2005). In 2009 The Waste Framework directive (2008/98/EC) outlined some basic waste management principles, and provided definitions for waste, recycling, and recovery (EU Commission, 2008). In February 2015, the EC released its action plan for the CE, in which "the value of products, materials and resources is maintained in the economy for as long as possible, and the generation of waste minimised." An approach believed essential to "develop a sustainable, low carbon, resource efficient and competitive economy" (EU Commission, 2015).

Fig. 2 Schematic of the product life cycle.

A macro level view of the CE concept coupled with a basic understanding of the objectives of LCCA and LCA methodologies would suggest an almost ideal synergy to achieve common goals, and this is true to some extent. LCA and LCCA allow management to test the assumptions of their CE business models, identify limitations, and formulate plans for continued improvement. However, a more detailed examination reveals areas where interpretations and subsequent recommendations may not align perfectly. Dieterle *et al.* (2018) suggest that CE [circular economy is referred to as C2C in the Dieterle report] and LCA objectives and recommendations may diverge in cases where trade-offs exist between energy and material use. In their example, substituting the primary materials used in the housing of an electric car engine with recycled material, contributes to closing the material loop, and complies with the CE concept; however, the recycled material may be lower in mechanical value requiring more of it to be used, thus, increasing the overall weight of the vehicle and contributing to the impact of increased energy consumption during the vehicle's use phase. This puts CE and LCA recommendations in direct conflict. However, it should be noted that the magnitude of impact from energy use is as dependent on the source of energy generation, as it is on the amount of energy consumed. Similar assertions could be made based on the results of the study conducted by Faludi *et al.* (2015). Additive manufacturing (AM) or "3D printing" is perceived as having *environmental benefits* when compared with other processes – in this case computer numerical control (CNC) machines. The research team chose LCA to test this thesis. The results of the study were to some degree inconclusive in determining the most "sustainable" solution due to the effect of variations in usage profiles and machine types. However, without any reference to CE in the study, it could be understood where LCA and CE recommendations would diverge. The CE approach on its own would not yield a fair or comprehensive environmental assessment in this type of study. AM is generally less material intensive than CNC milling, in the sense that less waste material is produced (Huang *et al.*, 2013). The cutting oils used in CNC machines are reported to pose significant health and environmental risks (Childers, 2006). The AM process does not use cutting oils but does have other chemicals that are used in their model materials, the impact of which has not yet been fully examined. From a CE perspective the reduction in material flow would appear to be the favorable option. However, this type of analytical approach provides only one part of the system's environmental profile. For example, it is claimed that some AM processes can require up to 50% of virgin material to be used along with recycled material, and that the AM materials can have a higher ecological impact per unit mass than CNC materials (Telenko and Seepersad, 2012). Additionally, AM processes are generally more energy intensive, which is not captured with CE, or at least not given the same weight of importance as closing the material flow cycle, whereas LCA operates with a much broader scope of energy, material, and waste flows.

The Faludi study highlights the importance of expanding the scope of comparative analysis to include the impacts from all of the flows associated with both manufacturing processes. Used in isolation, the CE approach as a decision support tool has its limitations. From an LCA perspective these limitations could be viewed simply as boundary definition issues. Conversely, Dieterle *et al.* (2018) view LCA as containing *gaps* when approaching problems with the CE mindset. The recommendation suggested by Bakker *et al.* (2010) is that LCA should be used as a complementary tool to CE as a means to assess whether the focus of a study should be on materials or energy. Although arguments between advocates and detractors of both CE and LCA will undoubtedly continue into the future, it should be encouraging to all environmental practitioners that these debates exist. In a broader sense, the CE concept and LCA have more in common than separates them.

Additive Manufacturing, Commonly Called 3D Printing of Metals

The American Society for Testing and Materials (ASTM) defines the AM process as "[t]he process of joining materials to make parts or objects from 3D model data, usually layer upon layer, as opposed to subtractive manufacturing methodologies" (ASTM, 2009). The part is first designed as a CAD model before loading it to the 3D metal printer. In contrast, in the traditional subtractive process, a block of metal is machined by removing the material layer by layer by means of lathe or milling machines to produce the final part. AM describes a range of emerging production processes that have a high potential to enhance the capabilities of powder metallurgy production (Watson and Taminger, 2018; Dahmus and Gutowski, 2004; Morrow *et al.*, 2007; Chapman and Roberts, 1983; Walachowicz *et al.*, 2017; Wohlers, 2012). The process can be classified into seven technologies as shown in Fig. 3.

Among the seven AM techniques, a focus on metal powder printing is presented here due to its impact on industry and environment. In this process, the metal powder is deposited on the work platform mainly in two different ways blown powder and powder bed based techniques, Fig. 4. In the blown powder technique, the metal powder (or composite of powders) is fed onto the working stage and fused by the laser beam in the so called direct metal deposition process. In the case of the powder bed fusion (PBF), also called selective laser melting (SLM), the powder is spread and flattened on the work platform. The source of fusion in this process can be by a laser beam (SLM/PBF) or electron beam melting. The beam melts the powder in selective positions and coordination indicated by the CAD model. In both techniques, the working platform moves downward after the completion of each layer. The resolution of the movement is equal to the thickness of the built layer. Due to the mechanical stability of the metal powder, the unfused powder can largely be recycled and reused in a future production process.

The physical and mechanical properties of the produced part, such as surface roughness, dimensional accuracy, strength, coloring, surface hardness, and wear resistance are highly affected by the main processing parameters; see Fig. 5. These parameters include laser power, spot size, scanning velocity, hatch spacing/scan location, layer thickness, initial particle size, gas composition, flow rate, and powder bed temperature.

Fig. 3 The current technologies used in additive manufacturing.

Fig. 4 Schematic of the direct energy deposition and powder bed fusion additive manufacturing processes.

Rapid manufacturing of metal components by laser forming. *International Journal of Machine Tools and Manufacture* 46 (12–13), 1459–1468.

Process Features

Advantages

The process enhances manufacturing by reducing lead times, manufacturing on-demand (reduce inventory and associated overheads), parts can be manufactured at internal/external customer's location to reduce shipping and logistics expenses, no material wasting, flexible design with no or less trials, products can be manufactured with fewer parts to reduce assembly, customized mass production, the ability to manufacture parts with complex geometry due to the no-tooling constraints, and new material compositions and multimaterial part production.

Disadvantages

Inconsistency and nonisotropic chemical and mechanical properties compared with traditional manufacturing can result due to the temperature and thermal gradient between the consecutive layers, high cost of machines and feedstock materials, lack of appropriate quality assurance, and development with lack of experience on some products and metal composites, in most cases limited build volume and constrained types of materials due to tool compatibility, parts with complex geometry might need supporting elements and postprocessing and subsequent heat treatment might be essential, that is, thermal stresses release, hardening, annealing, and surface polishing in addition to the high cost regarding the powders production.

Case Study

Problem and additive manufacturing solution

In Washington State, English Racing was struggling with their Mitsubishi 4G63 race engines (3D systems). The car reaches maximum speed of 185 mph in less than half a mile and an engine rotation of 10,000 rpm. This high level of rpm resulted in excessive oil pressure, which in turn would destroy the engine. Therefore, the design engineers decided to reduce the rotational speed of the oil pump to reduce the oil pressure inside the engine. To reach this solution, a bigger diameter driving pulley had to be manufactured and installed on the oil pump. The original pulley design was a part manufactured by melt injection molding requiring expensive tooling, time and money. After two years of trials, the part was made on a Prox DMP 300 3D printer. The working prototype took only five hours to print.

Tightening the Loop for the Circular Economy

In comparison with the most traditional (subtractive) manufacturing processes, additive manufacturing offers the ability to serve better in terms of the CE; see Fig. 6. In all types of AM processes, a high percentage of the unused material can be recycled and used in the next manufacturing process as a 100% virgin material. For many applications it is considered that only the metal powder attached to the produced part outer surface may suffer from excessive oxidation and change in its properties due to the high exposure temperature. For this reason, the later portion of the powder is preferably mixed with a fresh virgin powder to avoid the inconsistency in physical and mechanical properties, which might lead to part failure.

In the subtractive manufacturing, most of the waste metals are in cut metal chip form, cannot be remelted, and are difficult to handle and transport. Fig. 7 shows an example in which excessive waste chip material is generated by conventional manufacturing. In AM, only the exact amount of metal powder required to build the part is consumed, unlike the linear take–make–waste model. Obsolete and faulty parts from both processes can be recycled and used as raw material in most scenarios.

Fig. 6 Schematic of the linear, reuse, and circular economy modes.

Fig. 7 Shows the amount of waste material that can result from traditional machining operations. Reproduced from Watson, J., Taminger, K., 2018. A decision-support model for selecting additive manufacturing versus subtractive manufacturing based on energy consumption. *Journal of Cleaner Production* 176, 1316–1322.

State of the Art in the Energy Consumption and Cost

One of the major drawbacks in additive manufacturing is the high cost of feedstock metal powders. The following [Tables 1–3](#) list the market pricing for some of the common metal powders used in AM, the energy consumption for different manufacturing processes and the hourly machining rates and labor cost. The specific energy consumed during the production of the raw material, powder atomization, and the related machining processes are listed in the following [Table 2](#). The production rates including the labor cost and tooling for various manufacturing methods are presented in [Table 3](#).

In the case of subtractive manufacturing, the production machine consumes a variable amount of electric energy depending on the material being machined, the feed rate, the spindle rate, and the tool configuration. In addition, there must be a substantial amount of energy, which is constantly consumed when the machine is on the standby mode during the tool and workpiece set-up even though the cutting operation is not initiated. This energy is required to run the axes motors and spindle drive, oil lubrication and hydraulic pumps to maintain their pressure levels, lighting, and CNC electronic boards. Sometimes the machine stays on the standby mode for several hours before processing the material. It is necessary to reduce this idle time to minimize the energy consumption.

In contrast, the energy consumption in the 3D printing machines includes the energy required for maintaining a continuous delivery of the metal powder, running the positioning stage motors, supplying the heat source (laser beam or EB) and running all the control sensors, extraction and vacuum systems, electronic boards and lighting, and any embedded heating elements. This energy consumption is different from one machine to another. It is difficult to compare between different 3D printing machines in terms of energy consumption. [Watson and Taminger \(2018\)](#) identify many reasons why this is difficult to do due to the different experimental set-up between researchers, such as the differences in the thermophysical properties of the printing metal from one research project to another and different part designs. The processing parameters were also not always optimized when these results were obtained.

Table 1 Market prices for selected metal powders used in AM

<i>Metal type</i>	<i>Powder (€/100 g)</i>
316L SST	402
316 SST	135
304 SST	157
Iron	10
Copper	80
Titanium	300

Kamps *et al.* (2018) developed two models to compare the cost and energy efficiency for the manufacture of a gear by SLM against two other industrial processes, hobbing and milling, depending on data collected from literature and for a production volume of up to 1000 pieces. The cost model included the cost for annealing and the removal of the residual stresses, removing the part from the platform by wire Electron Discharge Machine or sawing machine, machine rate and depreciation, argon gas

consumption, and the cost of the metal powder. Fig. 8 shows the total Laser Beam Melting (LBM) manufacturing cost per part as a function of the mass and the recycle rate for a production volume of four gears.

Fig. 9 shows several break-even points for one of the subtractive methods and the SLM depending on the size of production and the mass of the gear parts produced. Also, it can be concluded that SLM is an efficient alternative for small mass and small size of production (up to 43 pieces). For the larger mass of 1.1 kg, only small production capacity of four pieces is a good cost option, which can be compared with the milling of a 0.8 kg gear.

When investigating the life cycle analysis for this case of gear production, it was found that the production volume had no significant effect on the average specific energy consumption. Also, the employment of a dual laser source embedded in one SLM

Fig. 10 The energy embedded of three manufacturing processes of a metal gear for the different production volume. Reproduced from Kamps, T., Lutter-Guenther, M., Seidel, C., Gutowski, T., Reinhart, G., 2018. Cost-and energy-efficient manufacture of gears by laser beam melting. CIRP Journal of Manufacturing Science and Technology 21, 47–60.

Fig. 11 The embedded energy and cost of the three processes for production volume of up to 20 parts. Reproduced from Kamps, T., Lutter-Guenther, M., Seidel, C., Gutowski, T., Reinhart, G., 2018. Cost-and energy-efficient manufacture of gears by laser beam melting. CIRP Journal of Manufacturing Science and Technology 21, 47–60.

machine is beneficial due to the doubling of the melting rates knowing that all the auxiliary equipment such as motion motors, control system, lubrication, powder feeding, and heating are shared between the lasers. The adoption of a lightweight part design in this case was found to be not a significant factor as it only increased the overall energy consumption by 3% compared with milling cavity holes to reduce the total weight from 1.1 to 0.8 kg as shown in A and B in Fig. 8. Fig. 10 shows a direct comparison of the embedded energy (E) for the three production processes.

As can be seen, at low production volumes, the hobbing process shows high embedded energy due to the extensive tooling necessary and decreases by increasing the production capacity. Both milling and LBM processes show constant energy levels for the different production sizes. It is clear that the lightweight parts (B and C in Fig. 8) require less energy.

At this stage, a direct comparison between the three processes in terms of the cost and energy consumption is beneficial as shown in Fig. 11.

The figure indicates that LBM is a good option for the low production capacity of <12 parts when taking into account the two models, cost and life cycle analysis based on the areas below the cost and energy plots. This means that LBM can be recommended for manufacturing of high variance models and designs such as aerospace.

Making a decision for which manufacturing process is more efficient for the production of a certain model designs and metal can be utilized by investigating the total cost and the life cycle analysis. These analyses in turn are highly related to several factors including design complexity, metal cost, processing parameters and their levels, machining cost rate, equipment, and tooling. The energy consumed must be measured experimentally and divided by the volume of material being added or removed for a direct comparison (Kamps *et al.*, 2018). The energy consumption in LBM technology comprised only 4% of the overall production cost. The material losses and tooling are significant factors in the conventional methods like milling, hobbing, and lathe. Additionally, postprocessing must be taken into account, which in most cases has high importance to adjust the final dimensions or surface finishing such as milling, grinding, and polishing or to release the surface thermal stresses and heat treatments such as annealing and hardening.

Finally, the SLM manufacturing method is now considered a mass manufacturing technique. Several companies are employing it for the production of many parts such as Boeing using this method for the manufacture of more than 200 parts on 10 production platforms (Huang *et al.*, 2013). This is a very important achievement attributed by the reduction of the AM parts weight, that is, it estimated that the reduction of the aircraft overall weight reduces the energy consumption by 2800×10^{15} J/year and the associated CO₂ by 215×10^6 MT/year (Huang *et al.*, 2016).

It is clear that in many cases, the metal AM process reduces the environmental impact and provides for increased manufacturing sustainability. It does not use water for cooling so no damage is caused to the terrestrial or aquatic system. It requires much less warehousing and transportation as material is requested according to the manufacturing specifications and on customers' demand and could be produced at the customer site, such that files are shipped rather than excessive shipment of materials or parts.

A Comparative Life Cycle Assessment for Utilising Laminated Veneer Bamboo as a Primary Structural Material in High-Rise Residential Buildings

Philip Kavanagh, Jim Roche, Noel Brady, and John Lauder, Dublin School of Architecture, Dublin, Ireland

© 2020 Elsevier Inc. All rights reserved.

Glossary

Biomimetic The imitation of the models, systems, and elements of nature for the purpose of solving complex human problems.

Eco-Cost A measure to express the amount of environmental burden a product or system has. Represented in terms of Euros per kilogram i.e., €/Kg.

Global Warming Potential (GWP) (kg CO₂ eq) A measure of greenhouse gas emissions, such as CO₂ and methane. These emissions are causing an increase in the absorption of radiation emitted by the earth, increasing the natural greenhouse effect. This may in turn have adverse impacts on ecosystem health, human health, and material welfare.

Introduction

The aim of this research project is to establish, through a structural comparison review and comparative life cycle analysis (LCA), the overall contribution that laminated veneer bamboo (LVB) has to global warming potential against that of cross laminated timber (CLT). This study also aims to establish if engineered bamboo is a feasible alternative construction material for use in high density urban housing in a European context.

The project aims to achieve the following objectives:

- (1) Collate and critically analysis and data from the field of bamboo and laminated veneer bamboo.
- (2) Establish through structural data comparisons the potential for engineered bamboo products to be implemented into high rise construction.
- (3) Research the embodied carbon of LVB and CLT and apply this to the Life Cycle test results.
- (4) Conduct a comparative Life Cycle Analysis (LCA) on laminated veneer bamboo (LVB) and cross laminated timber (CLT) to assess the global warming potential of both.

Literature Review

Product (Laminated Veneer Bamboo)

Laminated veneer bamboo (LVB)

Laminated veneer bamboo (LVB) is a product that uses multiple thin strips of bamboo combined with an adhesive to form a board or sheet product. Manufactured by Glubam, Moso and Lamboo® Inc. to name but a few it typically consists of 3, 5, 7, and 9 layers laminated veneer bamboo is manufactured in a similar way to OSB or Plywood. A series of thin strips of bamboo are laminated together in alternating 90° angles for each layer.

The production of LVB can be divided into the following steps:

Slicing of bamboo poles longitudinally to create strips of bamboo. Strips are produced by feeding culms through a splitter machine that cuts the bamboo culm into slender strips.

Surfaces of the strips are scraped and planed to remove wax and silica as well as to create rectangular cross sections.

Strips are left to air-dry at room temperature for one week after they are cut.

Air-dried strips are then immersed in a boron solution and left to dry in the sun until their moisture content reach 12%.

Adhesive is applied to the strips that are then neatly arranged next to and on top of one another to create the final product.

Bamboo sheets are produced by placing bamboo strips side-by-side and edge-gluing them using tannin resorcinol formaldehyde (TRF) (Mahdavi *et al.*, 2012).

Fig. 1 below shows a graphical breakdown of the process.

Mechanical Properties

Bamboo as a material has been used in small local developments predominantly in Asia and South America for millennia. It is undeniable that bamboo has the capability to be considered as a structural material in its raw natural form. Many studies have been conducted on the application of bamboo in its natural form for construction purposes. A study by Albermania *et al.* (2007)

Fig. 1 Manufacture process of Laminated Veneer Bamboo. Reproduced from Rittironkand, S., Elnieiri, M., 2015. Modern bamboo structures. In: Investigating Laminated Bamboo Lumber as an Alternate to Wood Lumber in Residential Construction in the United States. Taylor & Francis, pp. 83–96.

on a lightweight bamboo double layer grid system indicate that, in practice using a special PVC jointing system devised by the team, these double layer grid systems could be applied for the construction of designs of small to medium span buildings (Albermania *et al.*, 2007). Furthermore, a study conducted by Yu *et al.* (2003) on the column buckling of structural bamboo demonstrates that “The proposed design method applied by the researchers is shown to be structurally adequate in accordance with modern structural design philosophy, and it may be used effectively, to correctly and appropriately design structural bamboo (*Phyllostachys Pubescens* & *Bambusa Pervariabilis*) in bamboo scaffolds and other bamboo structures”. This study along with the availability of design data on the dimensions and the mechanical properties of structural bamboo, in its natural form, allowed structural engineers to take the advantages offered by bamboo to build “light and strong bamboo structures to achieve enhanced economy and buildability” (Yu *et al.*, 2003).

These studies show the potential use of bamboo in its raw natural form.

The following is a comparison of board/sheet products under different mechanical properties; flexural and compressive strength, modulus of elasticity, shear strength and tensile strength. The mechanical properties for each of the materials in question were sourced from the market leading companies that produce these products. The values and figures presented were extracted from data sheets provided by SmartPly OSB/Plywood and by Lamboo® Inc. None of the mechanical properties presented were the result of any testing conducted by the author of this research or any persons associated with this research. The comparison of the materials and all comments associated to the comparison are the work of the author.

In order to ensure a comparison can be made between these products the means by which they are tested must first be evaluated. All materials were tested to ASTM international standards and sample sizes were manufactured according to ASTM 3501 for compressive strength testing, ASTM 3500 for tensile testing, ASTM D3043 for flexural testing, ASTM D3048 for shear testing and ASTM D 1037 for determining elastic modulus. ASTM international is an internationally recognised standards organisation. The ASTM testing of materials is similar to testing set out by The International standards organisation (ISO) and Eurocodes who follow the guidelines set out by ISO. The data was critically reviewed and test methods were evaluated against those of European Standards. This process was carried out as the majority of the research for bamboo specimens was conducted using an American standard for testing materials (ASTM) now ASTM international (ASTM, 2012; Lamboo, 2014). This review of standards showed identical testing procedures when compared to European standards. Relevant data was compiled and presented to show the capability of LVB against similar building products for instance Plywood and Orient Strand Board (OSB).

Test Specimen sizes for testing of board products are presented at the beginning of each sub-article. A thickness of 12 mm has been given to the laminated veneer bamboo. All other materials are presented with their thickness.

From the simple comparisons in Table 1 we can see that the laminated veneer bamboo product excelled in all but one of the test areas.

A full break-down of the data in the graphs previous is depicted in Table 1.

It is fundamental that if laminated bamboo is to be considered as a usable building material further research is needed on the mechanical properties of the sheet material including and taking into account a factor of safety. Furthermore, how the material is used i.e., as a sheet material, in a column or beam system or in a panelised system could change the structural characteristics of the material. This is particularly noticeable when using the material for high rise construction where the members used in the lower stories will be under considerably more load than that of the members used in the upper storeys of a buildings structure. The behaviour of the different ways LVB could be used needs further research and set of mechanical data need to be established for each system design as described in the panelised design later in this report. In terms of a general comparison of mechanical properties of LVB and other widely used timber sheet materials, please see table below:

Table 1 Comparison of mechanical data sheets for LVB, OSB and Plywood. Comparison of mechanical data for OSB, American Plywood, Swedish Plywood and Laminated Veneer Bamboo panels

Structural characteristics		Laminated Veneer Bamboo (LVB)	6–10 mm OSB	10–18 mm OSB	18–25 mm OSB	12.5 mm American plywood	21 mm American plywood	21 mm Swedish plywood	25 mm Swedish plywood

Table 2 Description of life cycle stages

Profile Type	Life cycle stages included	Study units	Use for comparison	Responsible party
Cradle to gate	Production stage (raw material supply, transport and manufacturing of products and all upstream processes from cradle to gate)	Information module: Per tonne	Shall not be used for comparison	In-factory (gate to gate) data collected by manufacturer Per-factory data for raw materials provided by BRE Certification Ltd
Cradle to site	Production stage (raw material supply, transport, and manufacturing of products and all upstream processes from cradle to gate. Construction process stage (transport to the building site and wastage from building installation/construction only) including transport and disposal of waste.	Information module: Per meter ² installed element	Shall not be used for comparison	As above and Construction process data provided by BRE Certification Ltd
Cradle to grave	As above and Use stage: Repair, replacement, maintenance and refurbishment including transport of any materials and disposal of waste over the 60-year period. Demolition: is expected to occur at any time at or after the end of the study period and it includes transport and disposal of waste.	Functional Unit: Per square meter installed element over a sixty-year period in the building	Can be used for comparison if the functional unit is equivalent	As above and Life time data by BRE Certification Ltd

Note: ISO, 2013. 'ISO 14040:2006 – Environmental management – Life cycle assessment – Principles and framework'.

Life Cycle Analysis: A Review

Life cycle assessment (LCA) is an internationally recognised method for assessing the potential environmental impact of a certain material or process for its entire life cycle (Cradle to Grave/Cradle) or part of that life cycle (Cradle to Gate). A life cycle assessment is completed, by:

- Compiling an inventory of relevant energy and material inputs and environmental releases,
- Evaluating the potential environmental impacts associated with identified inputs and releases,
- Interpreting the results to help you make a more informed decision (US EPA, O., Sustainable Technology Division, 2012).

Life Cycle assessments are broken down into different profile types. These profile types are shown in Table 2 on the following page. These profile types define the parameters and extents of a life cycle study or system boundary.

There are four phases in an LCA study:

- The goal and scope definition phase,
- The inventory analysis phase,
- The impact assessment phase, and
- The interpretation phase.

Cradle to Cradle

Cradle to cradle design is a biomimetic approach to the design of products and systems. It models the human industry on nature's processes viewing materials as nutrients circulating in healthy, safe metabolisms (Braungart and McDonough, 2008).

In relation to the subject here a cradle to grave profile will be selected for the ability to compare different design/material options. The materials in question will be bamboo as it is manufactured into usable building products and timber as it is manufactured into usable building products. These building products will then be applied to an architectural design and building method and eventually be evaluated at the end of life phase. The stages of the life cycle that will be assessed are as follows:

- Raw material extraction,
- Product manufacture (Laminated Veneer bamboo) and associated emissions,
- Building Applications,
- End of life and associated emissions.

Transportation

Transportation of goods and its environmental impact is far beyond the scope of this research yet has a big impact on the life cycle of a material or product. In relation to sourcing bamboo from Vietnam or China a large quantity of the CO₂ emissions and overall environmental impact will be caused by the burning of fossil fuels in the transportation of the material to Europe from these areas of the world.

In the study by Van der Lugt et al this is the second highest contributor to eco-cost (28%–37%) and carbon footprint (15%–25%) depending on the material which is transported. Unavoidable for the European context, it is suggested that bamboo could be sourced closer to the location of use in areas such as Ethiopia or Central Africa reducing the effect of transportation by sea freight to Europe.

Local transportation contributes to approx. 10% of the eco-burden (Vogtlander and van der Lugt, 2014).

This figure, whatever it may be, will be constant and unavoidable and will likely contribute negatively towards the overall GWP of LVB and hence its integration into designs and buildings in Europe. In another study conducted at Delft University, Netherlands, by Vogtlander et al. (2010) transportation of bamboo poles from Shanghai harbour to Rotterdam harbour in the Netherlands contributed to 89% of total emissions (Vogtlander et al., 2010; van der Lugt et al., 2012).

In this study Vogtlander et al. (2012) measured emissions in terms of eco-cost. The eco-cost of a material is a measure to express the amount of environmental burden a product or system has. It is represented in terms of Euros per kilogram (€/Kg) and in simple terms is the amount of money that would need to be invested in renewable technologies or environmental strategies to mitigate the CO₂ emissions of the material tested.

The results from the report by Vogtlander et al. (2012) can be seen in Table 3 below.

The eco-cost of shipping equated to 25% of the total environmental burden of 3-layer plybamboo. Adding this to the other transportation steps in the process that equate to 20.4% the total contribution is 45.4%. This highlights that the carbon emissions due to transportation are still a major contributor to the overall global warming potential of bamboo products.

Table 3 Transportation Environmental impact (Eco-Cost)

Environmental impact assessment of carbonized 3-layer Plybamboo board

<i>Process step</i>	<i>Amount</i>	<i>Unit</i>	<i>Eco-cost (€/unit)</i>	<i>Eco-cost (€)/ Functional unit</i>	<i>Eco-cost (€)/kg</i>
Transport from plantation to strip manufacturing facility; Eco-costs of a 5-ton truck (transport of 92.4 FUs)	30	Km	0.243/km per 5 ton truck	0.316	0.0075
Transport from strip manufacturing facility to factory; Eco-costs of a 10-ton truck (transport of 310.4 FUs)	600	Km	0.32/km per 10 ton truck	2.474	0.059
Transport from factory to harbour; Eco-costs of a (28-ton truck)	3.13	ton.km/FU	0.033/ton.km	0.1032	0.0099
Transport from harbour to harbour; Eco-costs (20 ft container in a trans-oceanic freight ship)	200.24	ton.km/FU	0.0052/ton.km	1.0413	0.0999
Transport from harbour to warehouse; Eco-costs (28-ton truck)	1.2	ton.km/FU	0.033/ton.km	0.0396	0.0038

Fig. 2 Case study: Stadthaus, Murray Grove, London.

However, newer more efficient proposals for transporting goods, in particular one for a 'New Silk Road' Railway from 'east to west China, routed through Kazakhstan, Russia, Belarus, Poland, Germany, France and finally to Spain' (Dispatch, 2014) present an interesting argument that if transportation of goods becomes more efficient and produces less pollution then the overall contribution of the transportation stage to carbon footprint can be reduced. This efficient manner of acquiring goods will have a beneficial effect on the time frame of a project resulting in better, cheaper more efficient building projects and potentially lower carbon emissions. However, this area requires further specialised research.

Primary Research

Case Study (Stadthaus, Murray Grove)

Completed in 2009, the multi award winning, Stadthaus at Murray Grove is a nine story residential building located in Hackney, just north of the city of London. Consisting of both private and affordable apartments it is, according to the cross laminated timber company KLH, the "pioneer of timber residential tower buildings in the world" (KLH, 2015) (Figs. 2–4). The entire structure comprises of 29 apartments.

The entire tower is constructed using a series of Cross Laminated Timber panels produced by KLH which "form a cellular structure of timber load bearing walls" and "timber floor slabs" (KLH, 2015).

Stadthaus is currently one of the tallest habitable residential timber buildings in the world. Through the selection of timber as the primary construction material the design team were able to reduce the carbon footprint of the building in a number of ways.

"The designers calculated that had the building been of conventional reinforced concrete construction, it would have incurred an additional 124 tonnes of carbon generated during construction. Adding this to the 188 tonnes of carbon sequestered (locked away) (during the growth of the tree) in the 900 m³ of timber in the structure results in a total offset of some 310 tonnes of carbon" (TRADA, 2009). This offset allowed for the planning authority to grant a dispensation from the 'Merton' rule which usually requires that 10% of the energy for the building and its occupants be generated on-site using renewable energy equipment (Merton, 2015) (This rule has since been superseded by new amendments to the building regulations under Part L.).

Furthermore, the speed of construction using this method of cross laminated timber is also worthy to note with regards to the installation cost and emission caused during this phase as part of the life cycle assessment of the building. The entire super structure was erected within 27 working days. The entire building programme for the CLT build was 49 weeks, 7 weeks of which were for the erection of the CLT superstructure, 23 weeks shorter than if an equivalent concrete building had been constructed (KLH, 2015). This rapid building process again results in a positive outcome when it comes to the energy and carbon emissions associated with building construction.

Development of Panelised Building System

For the purposes of this research a standardised panel system has been developed to compete with cross laminated timber (CLT) panels. The initial panel system as seen in the images (Figs. 5 and 6) below utilised laminated veneer bamboo (LVB) ply sheets in an efficient manner to exploit the structural characteristics of LVB ply. This system was designed to be a series of interlocking pieces which could be efficiently cut using CNC and assembled either on site or in factory controlled setting and then transported to site fully assembled. Panels are glued and screwed to ensure a strong connection is made between each of the elements.

Fig. 3 3D Cross section of Stadthaus. Reproduced from KLH, 2015. KLH: Stadthaus, Murray Grove. Available at: <http://www.klhuk.com/portfolio/residential/stadthaus,-murray-grove.aspx> (accessed 31.07.2015).

Fig. 4 Internal view of CLT construction at Stadthaus. Reproduced from KLH, 2015. KLH: Stadthaus, Murray Grove. Available at: <http://www.klhuk.com/portfolio/residential/stadthaus,-murray-grove.aspx> (accessed 31.07.15).

Each panel comprises of two full 2440 mm × 1220 mm sheets (A) with studs or 'ribs' (B & C) placed at regular intervals in between the two sheets. Each panel was designed to efficiently use a 2440 mm × 1220 mm sheet. **Figs. 7** and **8** below show the cutting setup for each sheet that is required to assemble a single panel. **Table 4** shows a breakdown of the parts required.

Based on the comments by the specialist advisor and engineer, John Lauder, changes were made to the design of the panels. The changes are listed below:

- Panels are now designed without joints. Comments were made suggesting that the joints were not particularly necessary to ensure a connection between elements.
- The thickness of the studs or 'ribs' was increased from 12 mm to 24 mm. This was done to ensure there was no cracking or damage to the stud as the screw connection is made. Panels are now designed with pilot holes for screws and changes have been made to the thickness of the studs.
- Suggestions were also made to include a certain amount of bridging between the studs to minimise the potential buckling effect and provide the panel with extra rigidity.
- Completely enclose panel system with a footing piece and top capping piece. These like the studs will be 24 mm thick and 1220 mm long to fully enclose the panel. By placing a capping piece and a footing the overall height of the panel is increased to 2488 mm (2440 mm + 24 mm top and bottom).

Fig. 5 First design – Laminated veneer bamboo Panel System. Reproduced from KLH, 2015. KLH: Stadthaus, Murray Grove. Available at: <http://www.klhuk.com/portfolio/residential/stadthaus,-murray-grove.aspx> (accessed 31.07.15).

- The main face sheets (A) remain at 12 mm thick.
- Comments were also made that panels should not be restricted to a height of 2440 mm.

The revised panel designs much like the first concepts are each made up of two full 2440×1220 sheets with studs or 'ribs' placed at regular intervals in between the two sheets. The panel has a $1220 \times 120 \times 24$ mm footing at the base and is capped with a similar head piece to completely enclose the panel. The images (Figs. 9 and 10) below show the parts required to assemble the panel system.

The requirements for each one of the panels can be seen in Table 5 below:

Construction Details

Some typical construction details utilising the panelised system have been designed and can be seen in Figs. 11 and 12 below.

Primary Life Cycle Analysis

Scope

The scope of this study is to determine the global warming potential, through life cycle analysis, of laminated veneer bamboo diaphragm construction panels against that of cross laminated timber panels for use in high density high-rise residential accommodation.

Definition of Goal/Product System

As stated previously the main goal of this study is to determine the global warming potential of laminated veneer bamboo diaphragm construction panels over the selection of cross laminated timber panels. The following report is set up to the standards set out in ISO 14040 and the LCID handbook.

Using the Stadthaus at Murray Grove case study for high density high-rise residential accommodation, laminated veneer bamboo diaphragm (LVBD) panels have been substituted as an alternative to Cross Laminated Timber (CLT) panels (see design details and concept design from previous section). The product system to be studied, as mentioned in the goal of the LCA, is an

Fig. 6 First design – Laminated veneer bamboo Panel System (Wireframe).

application of LVBD Panels through a Cradle to Grave life cycle. The study will compare the application of LVB Panels to the current CLT option that has been utilised in Stadthaus, Murray Grove.

The life cycle testing is conducted on a full building model. As per the benchmark test conducted previously the testing is undertaken using an application, Tally[®], in conjunction with Autodesk Revit[®]. This application utilises reliable life cycle databases set up by PE international (now 'thinkstep'). Thinkstep is a provider of "the most comprehensive source of sustainability data in the world" with "72,000+ constantly evolving datasets compiled over 20 years" (Thinkstep, 2015). It provides the world's most up to date and reliable LCA data. The reason for selecting this platform to conduct the LCA was that it could be easily used in conjunction with a Revit[®]. By utilising skills in Revit the LCA application could easily take modelled materials and volumes from the Revit Families created for the projects and life cycle data could easily be applied to them in Tally[®]. Other applications like Gabi and Ecoinvent were explored and could have been used to conduct this study. However, the simplicity and ease of use of Tally[®] in Revit[®] was the reasoning behind its selection.

Functional Unit and Reference Flow

The functional unit is a measure of the function of the studied system and it provides a reference to which the inputs and outputs can be related. This enables the comparison of two essentially different systems (ISO, 2013).

The functional unit of the analysis is the usable floor space of the building under study.

The reference flow is the amount of material required to produce a building, designed according to the given goal and scope of the assessment, over the full life of the building. It is the responsibility of the modeller to assure that reference buildings or design options are functionally equivalent in terms of scope, size and relevant performance. The expected life of the building has a value of 50 years as manually specified by the modeller (Tally, 2015).

The System Boundary and Delimitations

The system boundary of LVB begins with the extraction of bamboo and ends with the disposal of the material at the end of its life cycle (*Cradle to Grave*). This system is depicted in graphical format in Fig. 13.

The manufacturing process includes all necessary life cycle data for the *cradle to gate* life cycle stages associated with the specific materials in the LVB and CLT design options.

Fig. 7 Sheet A – First design panel concept.

The life cycle analysis (LCA) accounts for the full cradle-to-grave life cycle of the design options studied, including

- Material manufacturing,
- Maintenance and replacement, and eventual,
- End-of-life (disposal, incineration, and/or recycling), including the materials and energy used across all life cycle stages.

Architectural materials and assemblies include all materials required for the product's manufacturing and use (including hardware, sealants, adhesives, coatings, and finishing etc.) up to a 1% cut-off factor by mass with the exception of known materials that have high environmental impacts at low levels. In these cases, a 1% cut-off was implemented by impact.

Manufacturing includes cradle-to-gate manufacturing wherever possible. This includes

- Raw material extraction and processing,
- Intermediate transportation, and
- Final manufacturing and assembly.

Due to data limitations, however, some manufacturing steps have been excluded, such as the material and energy requirements for assembling doors and windows. The manufacturing scope is listed for each entry, detailing any specific inclusions or exclusions that fall outside of the cradle-to-gate scope.

Transportation of upstream raw materials or intermediate products to final manufacturing is generally included in the GaBi datasets utilised within this tool. *Transportation requirements between the manufacturer and installation of the product, and at the end-of-life of the product, are excluded from this study.* However, the eco-cost of transportation had been evaluated previously in a benchmark test conducted as part of the overall study. It is noted within the benchmark test, bamboo is specified to be sourced from China to an unknown final destination and this may result in further discrepancies between the results. CLT does not specify a source destination or a final destination. For this reason transportation is again highlighted as an unknown quantity.

Fig. 8 Sheet B & C – First design panel concept.

Table 4 Initial panel design parts breakdown

<i>Criteria</i>	<i>Part A</i>	<i>Part B</i>	<i>Part C</i>
Number required per panel	2	2	3
Number of piece available per single 2440×1220 sheet	1	4	4

The data associated for transportation is an industry standard, an average. The data accounts for the average eco-cost and environmental burden for transportation of raw material to a product manufacturing site. The transportation from manufacturer to building site is not accounted for within the system boundary.

Infrastructure (buildings and machinery) required for the manufacturing and assembly of building materials, as well as packaging materials, are not included and are considered outside the scope of assessment.

Maintenance and replacement encompasses the replacement of materials in accordance with the expected service life. This includes;

- The end-of-life treatment of the existing products and,
- Cradle-to-gate manufacturing of the replacement products.

The service life is specified separately for each product.

End-of-life treatment is based on average US construction and demolition waste treatment methods and rates. This includes

- The relevant material collection rates for recycling,
- Processing requirements for recycled materials,
- Incineration rates, and
- Landfilling rates.

Fig. 9 Sheet A LVB panel system.

Along with processing requirements, the recycling of materials is modelled using an avoided burden approach, where the burden of primary material production is allocated to the subsequent life cycle based on the quantity of recovered secondary material. Incineration of materials includes credit for average US energy recovery rates. The impacts associated with landfilling are based on average material properties, such as plastic waste, biodegradable waste, or inert material. Specific end-of-life scenarios are detailed for each entry (Tally, 2015). Being a US company that develops the LCA tool European methods and rates were not available within the package. Thus, US rates were applied to the life cycle study.

Procedure

The following is an outline of the procedure undertaken to conduct the life cycle test. It includes the process of completing the Revit® Model and its subsequent use with Tally® life cycle software. The materials and definitions will also be outlined in this article and all assumptions and associated life cycle data will be clearly defined.

In order to conduct a life cycle with Tally® a 3D Revit® model must first be constructed and the modelled data and information extracted. Due to the convenience of using the two programmes together all data can be easily shared between the two. Data extracted from the Revit model to Tally includes:

- Materials
- Quantities
- Volumes
- Areas
- Weight

The entire model was built using simple components (Families) also designed and modelled within Revit®. For a full description of the procedure for the panel design can be found in the concept/design chapter (Section 5.0). A full list of these families can be viewed in the LCA report exported from Tally® in the appendix.

Using a similar process as the benchmark test two design options were modelled in parallel. Option A was constructed with laminated veneer bamboo (LVB) as the primary structural material while in Option B cross laminated timber (CLT) was designated as the primary structural material. These two models are depicted in Figs. 14 and 15 below.

It is of the utmost importance that the Revit® model is built with careful consideration as all values and quantities depend on the accuracy of the modelled elements.

The model of Stadthaus, Murray Grove, was constructed using a planning file submitted to Hackney council. (Planning application no. 2007/0988) Contact was made with Waugh Thistleton Architects to seek permission and information on the building. Though no additional information was received, an interest in the project was stated from the correspondence.

Fig. 10 Stud/Ribs (B) and top cap and footing (C).

The following outlines the elements included and those excluded from the Revit[®] model:

- For the purposes of this study *only the primary structural elements* were modelled. No secondary elements or finishes were applied to the model to ensure consistency. There is a large proportion of the as-built building not included in these models as this is a study on the structural building elements. And for that reason a portion of the overall impact of the overall building is not measured. *Only the structural elements were being tested in this LCA. Any other elements included are listed below.*
- No windows have been included in the model. However, openings have been included in the panels based on the elevations of the existing planning drawings.
- Curtain wall glazing has been included at the ground floor and at balconies.
- Internal doors have been included. Some doors have been placed in the model as independent elements and will show up in the LCA report as independent elements. LVB or CLT panels have been modelled to include doors and have been labelled appropriately in the report to show this. Doors have been modelled identically in both the LVBD and CLT design options. The doors were included in the model in order to ensure the volume of material in the door panel be it LVB or CLT was correct. This same principle applies to the openings cut in the window panel types.
- In both the LVB and CLT design options:
 - Wall panel thickness=128 mm,
 - Floor Thickness=146 mm,
 - Lift core wall thickness=300 mm (mass CLT or Mass bamboo in the bamboo options),
 - Stair core wall thickness=300 mm (mass CLT or Mass bamboo in the bamboo options),
 - Roof thickness=200 mm.

Impact Categories

The impact category under study in this LCA is Global Warming Potential (GWP). The global warming potential of a gas refers to the total contribution to global warming resulting from the emission of one unit of that gas relative to one unit of the reference gas, carbon dioxide, which is assigned a value of 1. This may also be commonly expressed as the 'Carbon footprint' of a material, product or unit output (US EPA, C. C. D, 2001).

The GWP of a gas or substance depends on the timespan or what is more commonly known as the time horizon. Since GWP is measured over a prescribed period of time, in this instance 50 years, gases may be removed from the atmosphere at a fast rate thus initially having a large effect but, over prolonged time periods, as it diminishes, it becomes less important.

For instance, as can be seen in table 56 below taking carbon dioxide CO₂ as a reference value and assigning it a value of 1, methane is assigned a GWP of 56 over 20 years. However, this drops to 21 over 100 years. The same applies to nitrous oxide N₂O starting at a value of 280 over 20 years but increasing to 310 over 100 years before decreasing again to 170 over 500 years. See Table 6 below.

A full list of gases and substance and their specific contributions to GWP can be found in the appendix (U.N, 2015).

Table 5 Revised panel system parts breakdown

Criteria	Part A	Part B	Part C

Fig. 12 Construction detail B (Not to Scale) (Parapet) for LVB panel system.

Life Cycle Impact Assessment

The life cycle impact assessment (LCIA) phase defines links between the life cycle inventory results and the potential environmental impacts (Puettmann, 2013). Fig. 16 below is a graphic representation of the LCIA impact categories of the project. Highlighted in red is the Global Warming Potential. This image also shows a comparison in the values associated to CLT and LVB in relation to an LCA not under consideration in this research. They include:

- Acidification potential,
- Eutrophication potential,
- Ozone depletion,
- Smog formation potential,
- Energy demand,
- Renewable and non-renewable energy.

Fig. 13 System Boundary for life cycle assessment.

Fig. 14 Cross laminated timber Design Option.

Table 14 presents the environmental impact of the two design options based on the case study model of Stadthaus, Murray Grove. The values found in Table 7 are the total cumulative effect of all the process associated in implementing LVB or CLT. These associated impacts include:

- Forestry or bamboo plantation management,
- Bulk commodity transportation,
- Manufacture of products and all upstream process (energy required at manufacturing plant, glues, finishing, etc.),
- End of life impacts.

Interesting to note is the higher values for the *sum of smog formation potential total* and the *sum of non-renewable energy demand total* in the bamboo LVB diaphragm box build. As part of the total primary energy demand also presented in the LCA results shown a section of that energy demand is deemed nonreplicable or replaced at a very slow rate by natural means (Jolliet, 2016). This non-renewable energy usually comes in the form of fossil fuels where in most cases energy dissipates in the form of unusable heat. As previously discussed, action could be taken to assign an eco-cost to all materials to reinvest in renewable resources to combat this issue. However, in the current situation it is noted as a factor against the use of engineered bamboo, a factor which is 41% for the bamboo LVB option compared to 27% for the CLT option. However, to counter this issue the overall primary energy demand of 8,296,976 MJ is circa 16% lower than the 9,798,998 MJ used in the CLT option. Similarly the sum of renewable energy demand is 58% of the total energy demand compared to circa 72% in the CLT option.

Also worth noting is the sum of smog formation potential. The bamboo LVB option contributes 33% more to this compared to the CLT option in this instance. Considering the effects that this can have on human health it is an issue that must be considered and

Fig. 15 Laminated veneer bamboo Design Option. Figures 14/15 above show 3D view of Revit® models created for Stadthaus, Murray Grove. These two models are identical in nature and size with the obvious difference in structural material and building method (i.e., Solid CLT or diaphragm panel where stated).

explored fully. Further research needs to be conducted on these areas to assess the differences between the two systems and their overall impact. As stated previously for this study, the global warming potential will be the main area of focus.

The entry source data or the data that was used to conduct the LCA can be seen below. The entry source data is provided by Thinkstep (formally PE International) within the Tally® application. For this LCA the data can be seen for each design option on the page over.

Bamboo diaphragm system

CN: Bamboo (estimation) PE (2012)

GLO: Bulk commodity carrier PE (2012)

US: Heavy fuel oil at refinery (0.3 wt% 0.3 wt% S) PE (2010)

CN: Electricity grid mix PE (2010)

DE: Phenol formaldehyde resin PE (2012)

Cross laminated timber

US: Laminated veneer lumber, at plant, US PNW USLCI/PE (2009)

US: Laminated veneer lumber, at plant, US SE USLCI/PE (2009)

Based on the identical designs and Tally® data input of Stadthaus at Murray Grove using cross laminated timber (CLT) and a laminated veneer bamboo (LVB) alternative, the results show that utilising a engineered bamboo diaphragm panel will result in a lower overall GWP. The LVB option out performs the CLT option by 33% or 207,975 kgCO₂eq. This lower GWP is based on the assumption that the LVB diaphragm panel system is structurally adequate to support the loading in a high rise construction. However, a range of values will be presented at the end of this should the diaphragm system not perform adequately.

Bamboo diaphragm system – 412,010 kgCO₂eq

Cross Laminated Timber – 619,985 kgCO₂eq

The Bamboo LVB diaphragm option out performs the cross laminated timber option in all three of the life cycle stages calculated as part of this study. See [Table 8](#) on the page over.

These three stages are:

- (1) The manufacturing stage; which includes the LCA data associated to all aspects of a *cradle to gate* LCA e.g., raw material acquisition, average transportation values of raw material to factory and all stages of the manufacture of the product/material.
- (2) The maintenance and replacement stage; which includes all environmental impact of constructing and maintaining the material over a 50-year period (the period of time defined within the Tally® application)
- (3) The end of life stage; which in both instances:
 - 14.5% recovered (credited as avoided burden),
 - 22% incinerated with energy recovery,
 - 63.5% landfilled (wood product waste) ([Tally, 2015](#)).

Table 6 Global warming potential of different gases

Species	Chemical formula	Lifetime (years)	Global warming Potential (Time horizon)		
			20 years	100 years	500 years
CO ₂	CO ₂	variable §	1	1	1
Methane *	CH ₄	12 ± 3	56	21	6.5
Nitrous oxide	N ₂ O	120	280	310	170

- Cross Laminated Timber

Fig. 16 Comparison of impact categories for LVB and CLT Design options 12 mm sheetsx128 mm depth (Generated from Tally Application as a result of specification of materials).

Table 7 Environmental impact of laminated veneer bamboo and cross laminated timber design options 12 mm sheets × 128 mm depth

Impact category	Bamboo LVB diaphragm box (primary)	Cross laminated timber
Sum of mass total (kg)	328,341	575,986
Sum of acidification potential total (kgSO ₂ eq)	4,103	4,955
Sum of eutrophication potential total (kgNeq)	634	1,046
Sum of global warming potential total (kgCO ₂ eq)	412,010	619,985
Sum of ozone depletion potential total (CFC-11eq)	0.0005	0.0011
Sum of smog formation potential total (kgO ₃ eq)	40,056	26,588
Sum of primary energy demand total (MJ)	8,296,976	9,798,998
Sum of non-renewable energy demand total (MJ)	3,433,224	2,692,059
Sum of renewable energy demand total (MJ)	4,863,753	7,106,939

Advancing on these initial results and to further compare the selection of laminated veneer bamboo a series of further models and LCA tests were conducted on different configurations of panels. These models were created based on feedback regarding the structural capabilities of the LVB system from advisor John Lauder and ARUP engineers. These models were designed with the following materials and configurations:

- (1) 24 mm thick LVB sheets used to create a typical panel size of 1220 mm × 2440 mm × 128 mm with bridging supports at c.400 mm. (Variations were modelled for windows and doors but followed a similar design with the area for windows and doors removed). This was tested against the Murray Grove CLT option also with 128 mm depth panels.
- (2) 24 mm thick *plywood* sheets used to create a typical panel size of 1220 mm × 2440 mm × 128 mm with bridging supports at c.400 mm. (Variations were modelled for windows and doors but followed a similar design with the area for windows and doors removed). This was tested against a mass bamboo solid panel option of the Murray Grove also with 128 mm depth panels.
- (3) Finally a hybrid option of *Mass bamboo solid panels* with 128 mm depth were placed on floors 1–5 and the *LVB diaphragm* panels place on the remaining 3 levels floor 6–9. This was tested against the Murray Grove CLT option also with 128 mm depth panels. This model was constructed based on feedback from ARUP engineers on the most likely outcome based on the limited knowledge of the structural capacity of the panels.

The results of these tests showed that:

- The global warming potential of the 128 mm plywood diaphragm panel with 24 mm sheets was lower than a solid laminated veneer bamboo panel. This is due to the reduction of material used in this system. A margin of 23% or approximately 136,368 kgCO₂e is seen in the plywood diaphragm panel system against that of the solid laminated veneer bamboo panel system.
- The margin is marginally greater as seen in the LVB diaphragm option when compared to CLT. A margin of 25% or 153,374 kgCO₂eq for the 128 mm depth laminated veneer bamboo diaphragm panel system with 24 mm sheets or 33% or 207,975 kgCO₂eq difference for the 128 mm depth laminated veneer bamboo diaphragm panel system with 12 mm sheets v's cross laminated timber panel system. In this case LVB comes out more favourably when compared to CLT.
- The 128 mm depth laminated veneer bamboo diaphragm panel system with 24 mm sheets design option still marginally outperforms the Plywood diaphragm design option by 2% or 9681 kgCO₂eq whereas the 128 mm depth using the 12 mm sheet outperforms the Plywood diaphragm design option by 13% or 64,282 kgCO₂eq.
- A similar result can be seen in the cross laminated timber and solid laminated bamboo design options. The mass LVB design option outperforms the CLT design option marginally by 2% or 7325 kg CO₂eq.
- Finally the Mass bamboo and 128 mm LVB diaphragm panel Hybrid building option (Mass LVB panels floor 1–5 & LVB panel floor 6–9) outperforms a CLT option by 25% or 88,171 kg CO₂eq.

The results in [Table 9](#) below show that, when compared to CLT, under the environmental conditions outlined at the beginning of the article, a laminated veneer bamboo alternative superstructure has the potential to compete with and surpass an engineered wood-based superstructure.

Furthermore, by implementing a more efficient use of materials which has been done in the LVB diaphragm design option GWP can be reduced by potentially 33% when compared to CLT.

Given the comparison of the options above highlighting that an LVB superstructure is marginally superior we can explore the implications of selecting a LVB option over a number of building projects in a year.

With the requirement for circa 20,000–30,000 new housing units required per year in Ireland this small margin, for even the worst case; 2% for Mass bamboo v CLT, would grow exponentially. In theory the more projects LVB is selected for the great the saving on GWP or kgCO₂e produced and outputted into the environment. This coupled with a managed plantation system and crop rotation for bamboo as well as an increase in FSC certified bamboo plantations as discussed previously (section 1.4),

Table 8 Comparison of Life Cycle Stages 12 mm × 128 mm depth

<i>Life cycle categories</i>	<i>Bamboo LVB diaphragm box (KgCO₂e)</i>	<i>Cross laminated timber (KgCO₂e)</i>
Manufacturing	193,412	287,985
Maintenance and Replacement	1,014	5,462
End of Life	217,582	326,538
Totals	522,751	723,743

Table 9 Global warming potential of 4 different building panel typologies for Stadthaus, Murray Grove, London

<i>Building construction type</i>	<i>Life cycle categories</i>			
	<i>End of life</i>	<i>Maintenance and replacement</i>	<i>Manufacturing</i>	<i>Totals</i>
128 mm bamboo LVB diaphragm box 12 mm sheets	217,582	1,015	19,341	412,010
128 mm bamboo LVB diaphragm box 24 mm sheets	247,601	1,015	217,995	466,611
128 mm plywood diaphragm box 24 mm sheets	271,758	1,015	203,520	476,292
Mass Bamboo and 128 mm LVB diaphragm panel	283,445	1,015	247,354	531,814
Hybrid option with 24 mm sheets				
128 mm mass solid laminated bamboo	298,338	5,462	308,860	612,660
128 mm cross laminated timber	326,538	5,462	287,985	619,985

means that a positive and more environmentally friendly approach to designing and building high rise residential buildings can be achieved.

A full breakdown of the life cycle impact of both the cross laminated timber and laminated veneer bamboo diaphragm design options can be found in the appendix.

Conclusions and Discussion

The aim of this research project was to establish, through a structural comparison review and comparative life cycle analysis (LCA), the overall contribution that laminated veneer bamboo (LVB) has to global warming potential against that of cross laminated timber (CLT). This study also set out to establish if engineered bamboo was a feasible alternative construction material to be used in high density urban housing. The following are the conclusions that can be drawn from the two major aspects of this research.

Structural Potential

It can be concluded from the structural assessment that engineered bamboo shows the potential to be implemented into mainstream construction typologies. The comparison of mechanical data supplied by Lamboo and SmartPly showed that LVB was a better performing material in all but one of the criteria. However, these values did come under some scrutiny and this shows that there is still a requirement to conduct full scale tests (as was intended as part of this research). Further research is needed to establish the mechanical properties of a panelised system. The panel system was designed and a lack of testing meant that some assumptions had to be made on its design and potential capabilities. Further research in this area should include:

- Manufacture panels (both solid and diaphragm panels) and conduct mechanical tests; compression, shear, tension and flexural on these full scale samples.
- Further research on how engineered bamboo should be implemented. Determine if a panelised system is the best application of engineered bamboo or if utilising bamboo in a post and beam system would be a better approach.
- Develop a set of building codes for use with engineered bamboo similar to those set up in *Eurocode 5: Design of Timber Structures*. By completing this it would ensure all standards and mechanical data is compiled for LVB structures and set up so as all buildings using this material are built safely and efficiently.

Environmental Assessment

This research reveals, through the environmental impact assessment of the case study model of Stadthaus at Murray Grove, London, and based on the criteria and system boundary set up for this study, engineered bamboo has a lower global warming

potential in relation to cross laminated timber. The following are the conclusions on the environmental impact of a bamboo panelised system:

If bamboo is implemented efficiently into a diaphragm panel system (128 mm depth) it can be up to 33% more efficient, in terms of kgCO₂e, than CLT.

If implemented into a solid panel system (128 mm depth) it can be up to 2% more efficient, in terms of kgCO₂e, than CLT.

If implemented into a hybrid system of a solid panel system (128 mm depth) and a diaphragm panel it can be up to 25% more efficient, in terms of kgCO₂e, than CLT.

It can be concluded that by implementing an engineered bamboo solution over a CLT solution on a similar building typology a reduction of between 2% and 33% can be achieved. Further research on the structural properties and capabilities of a panelised engineered bamboo building system may well reduce the percentage range presented. By first testing panel capabilities and then implementing the findings into the Revit model a more accurate set of data can be compiled.

Furthermore, the ability of bamboo to grow at a rapid rate of 3–5 years has major benefits on the environmental impact of harvesting it for construction purposes. With its ability to sequester larger amounts of CO₂ compared to timber, the results show that bamboo is a more favourable, environmentally friendly and sustainable material. With an increase in market share the values presented here will only continue to decrease in favour of bamboo. Additionally as previously suggested with the requirement for circa 20,000–30,000 new housing units required per annum in Ireland alone by implementing an LVB solution over a typical construction method the results could yield a major carbon footprint saving. The marginal difference between the LVB and CLT designs would grow exponentially for each project LVB is selected for. A similar observation, although not in relation to environmental impact, is made by De Flander and Rovers (2009) in their report previously discussed in the literature review that:

"If we compare this potential (of bamboo mainstream construction materials) with the construction market of The Netherlands for example, with a current number of around 60,000 new-built houses per year and with an estimated market share of timber-frame dwellings of about 5% (and growing), we could say that laminated bamboo frame houses could easily replace these 3000 timber-frame houses and/or even better, take over part of the other non-bio-based mainstream construction materials such as concrete and bricks" (De Flander and Rovers, 2009).

With a projected rise in population of 1.3–3.5 billion people by 2050, according to the UN, and the requirement to house the growing population a shift to more environmentally friendly, low GWP building materials needs to be considered in order to avoid further damage to the environment and a rise in global warming.

Introduction

Plastic Recycling

Plastics are used in a number of applications on a daily basis (Santibáñez *et al.*, 2007). Yet some plastic items end up in the waste stream after a single use only (single-life or cycle) or a short time after purchase, e.g., food packaging (Anastas and Zimmerman, 2006). Re-using plastic is preferable to recycling as it uses less energy and fewer resources (Allwood *et al.*, 2011). A number of techniques have been developed in order to separate and sort PSW (Beigbeder *et al.*, 2013). In the recycling industry, sorting and identification must be attempted within a short time to positively affect a recycler's finances (Schultz *et al.*, 1995). Further, plastic recycling can be classified as following:

- Primary recycling
- Secondary/Mechanical recycling
- Tertiary/Chemical recycling

Rapid Prototyping Technology

Rapid prototyping (RP) is the technology of making three dimensional (3D) models utilizing CAD models with minimum human intervention without any tooling requirement within reasonable time and cost (Mahindru and Mahendru, 2013). RP applications include the development of prototypes quickly within the time constraints (Pham and Gault, 1998). RP technology development leads to reduction in lead times for prototype manufacturing (Eppinger *et al.*, 1994). The major advantage of additive manufacturing (AM) processes is the manufacturing of intricate geometries in an efficient way (Rajurkar *et al.*, 1999). Other advantages of using AM technology include reduction in: total number of parts, mating and fitting problems, handling time and storage requirement (Liou, 2011).

RP is an additive manufacturing process of creating a solid part combining plastic layers (Levy *et al.*, 2003). Whereas, other machining processes like: milling, drilling, grinding etc. are subtractive processes of material removal from the solid piece (Zhu *et al.*, 2013). The additive nature of RP enables the easy production of intrinsic shapes with complex features (Peltola *et al.*, 2008). Wastage of material is highly controllable in this process. RP technology is highly preferred when limited quantity of pieces are required promptly in prototype manufacturing (Horn and Harrysson, 2012). RP has advantage in case of sub-assemblies as problem of fit and tolerance is highly decreased (Srikanth and Turner, 1990). RP technologies have numerous applications in various fields of medical sciences as well, as identified by various researchers in recent times (Cormier *et al.*, 2003; Bernard *et al.*, 2009). In mechanical engineering, RP technology is widely used in product development (Bernard *et al.*, 2009), die casting inserts (Baldwin, 1999), patterns and moulds manufacturing (Pal *et al.*, 2002), functionally graded material manufacturing (Jackson *et al.*, 1999; Dimitrov *et al.*, 2006) and making of end products (Hopkinson and Dickens, 2001; Santos *et al.*, 2006).

Various RP techniques are being used commercially (Schwarzenbach *et al.*, 2006). The basic principles of all RP techniques are almost same with some variation as per build material (Benardos and Vosniakos, 2003). The main steps involved in production of a part with RP techniques are shown in Fig. 1.

Fig. 1 Steps involved in production of a part with RP techniques.

Fig. 2 Classification of RP techniques based on phase of material.

Fig. 3 Schematic of FDM process. Reproduced from Singh, S., Bedi, P., Fraternali, F., Ahuja, I.P.S., 2016. Effect of single particle size, double particle size and triple particle size Al_2O_3 in Nylon-6 matrix on mechanical properties of feed stock filament for FDM. Composites Part B 106, 20–27.

Fig. 4 Process of FDM.

Rapid Prototyping Techniques

RP techniques are mainly classified under different categories on the basis of the phase of material used for pattern (Flanagan, 1954). The material to fabricate patterns with RP techniques are used in three different phases solid, liquid and powder based (Leong *et al.*, 2003). The various RP processes are shown in Fig. 2.

Fused Deposition Modeling

Fused Deposition Modeling (FDM) is a layer additive manufacturing process that can use production-grade thermoplastic materials in order to produce prototypes as well as end-use parts (Macdonald *et al.*, 2014; Bedi *et al.*, 2018). Fig. 3 represents the schematic of FDM process.

In FDM machine an extruder head moves in two principle directions following a predetermined path taken from the file (Jafari *et al.*, 2000). The extruder head contains heated nozzle with a small orifice, through which a semi-solid thermoplastic or wax filament is extruded (Ahn *et al.*, 2002). After each layer the table is lowered and a new layer is formed (Singh and Singh, 2015a,b). The new layer makes the bond with the previous layer and cools down as platform is maintained at a lower temperature as compared to nozzle (Kumar *et al.*, 2012).

The process, merits, demerits and applications of fused deposition modeling is mainly consisting of following three steps (Figs. 4 and 5):

The step by step methodology of whole study has been described in Fig. 6.

- (1) *Finding Melt flow indices for different sets of combinations of base matrix and reinforcements thereby selecting best combinations based on pilot MFI values.*

The melt flow index basically measures the rate of flow of molten melt of a thermoplastic polymer. It is defined as the mass of polymer (in grams) that flows through a path (capillary) of particular diameter and length in ten minutes by applying pressure through specified weights provided at prescribed temperature conditions.

- (2) *Preparation of filament wires using twin screw extruder (TSE)*

The twin screw extruder was developed more than 20 years ago, for continuous production of highly uniform and finely structure products. It is widely used to produce bio-sourced plastics, cellulose pulps and food products. For this study commercial make: HAAKE Mini CTW, Germany has been used.

- (3) *Mechanical testing of filaments on universal tensile machine.*

Tensile test is the most accepted test regarding judgment for quality of filament wire prepared. This test is performed on universal tensile tester to check the tensile strength at peak as well at break. Plastic wires, plastic flats or strip of any size can also be measured using universal tensile tester. The filament wires produced were tested mechanically on Universal Tensile tester (UTT).

- (4) *Fabrication of pins and RT on FDM*

The filament wires so prepared were fired into FDM (make: Divide By Zero's Accucraft i250D) setup. Divide By Zero's Accucraft i250D is a hybrid dual extruder 3D printer with a build volume of 200 mm × 250 mm × 200 mm.

Merits	Demerits	Applications
• easier production of parts with complex design features. • easier production of limited quantities customized parts • parts prepared are highly durable, strong, chemical and heat resistant • highly environment friendly technology • low maintenance costs	• ribbing effect i.e., very fine lines are seen due to deposition of each layer • the head of extrusion must be continuously moving otherwise material may start depositing and form lumps.	• Aerospace • Commercial • Automotive • Industrial • Consumer • Medical

Fig. 5 Merits, demerits, and applications of FDM.

Fig. 6 Methodology of study.

(5) *Wear testing of pins prepared using FDM*

A pin on disk apparatus generally includes a stationary pin of material to be tested and a rotating disk (with emery paper in this case). As the disk rotates with specific rpm, the stationary pin being in contact with the disk starts wearing out and thereby this information is transmitted through the sensors to the meter attached further being transferred to the software installed on the system. Using the Win Ducom Data Acquisition System, a PC acquires test data online and displays it in several ways. Graphs of individual tests can be printed.

(6) *Fabrication of RT on FDM*

Further, RT and work pieces (WP) were printed using FDM. Total 18 WP of diameter as 40 mm and thickness as 10 mm were prepared (09 WP of LDPE (100% by weight) without reinforcement and 9 WP of HDPE (100% by weight) without reinforcement). Similarly, 18 RT of $10 \times 10 \times 35$ mm were printed from wires prepared (as 9 RT of HDPE-TPS Al_2O_3 and 09 RT of LDPE-DPS Al_2O_3) on commercial open source FDM setup (Make: Divide by Zero). The printing temperature used for 3D printing of TPS reinforced HDPE RT was $170 \pm 5^\circ\text{C}$ and DPS reinforced LDPE RT was $155 \pm 5^\circ\text{C}$.

(7) *Machining of WP and RT using vertical milling to compute tool life.*

The discs prepared were used as WP for machining on vertical milling machine and tooling prepared was mounted perpendicular to WP for machining of RT.

(8) *DSC analysis of final RT prepared.*

Mettler Toledo DSC setup has been used in the study. Thermal analysis of various benchmarks prepared was done by using DSC technique and thermal plots were plotted correspondingly

(9) *Process Capability Study*

Process capability study in the present research has been used to realise the capability of the process by comparing the actual process spread with the allowable process spread and measured by process σ levels. In this work, process capability analysis was

carried out with the help of computer software (Process Capability Wizard Software, version. 1.7.0.0). The process capability has been visualized through the statistical measurements of C_p , C_{pk} and parts per million (ppm) non-conforming parts. C_p is a measure of a process's ability to meet a specification. C_{pk} is an index that measures how close a process is running to its specification limits, relative to the natural variability of the process. The larger values of C_{pk} represent that there are less chances that any item will go outside the specifications.

Experimentation

As a part of pilot study, Melt flow index (MFI) has been checked for different sets/combinations of HDPE/LDPE granules as base matrix with different sizes of SiC/ Al_2O_3 as reinforcements. It should be noted that the SPS represents single particle size (of either 300, 400, 500

Table 1 Final shortlisted combinations considering minimum MFI values

S. No.	HDPE	Al_2O_3 300-G wt%	Al_2O_3 400-G wt%	Al_2O_3 500-G wt%	MFI (g/10 min)

Note: Where, A is composition, B is Load (in kgf), C is temperature (in degree Celcius), D is RPM.

Bedi, P., Singh, S., Ahuja, I.P.S., 2018. Investigations for Rapid Tooling Prepared With Waste Polymer-Based Hybrid Filament. Reference Module in Materials Science and Materials Engineering. Oxford: Elsevier, 1–18.

American foundry society (AFS) grade), DPS represents two particle sizes in equal proportion by weight (of combination of either of two from 300, 400, 500 AFS grade) and TPS represents three particle sizes in equal proportion by weight (of 300, 400 and 500 AFS grade). Minimum values of MFI have been selected for each set of SPS, DPS and TPS combinations (as per pilot study) and summarized in [Table 1](#).

As per [Table 1](#), filament wires have been made from HDPE and LDPE on twin screw extruder with stated amount of reinforcements with the minimum values of MFI values (closer to MFI for original equipment manufacturer wire) as shortlisted.

[Table 2](#) shows various combinations of input parameters taken for study for HDPE and LDPE as per Taguchi L18 orthogonal technique:

The filament wires so produced as per [Table 2](#) have been tested mechanically on Universal Tensile tester (UTT). The results of UTT (Peak load, peak elongation, break load, break elongation, Young's Modulus) for HDPE and LDPE are computed and summarized in [Table 3](#).

The cylindrical pins have been printed on FDM with bed temperature as 55°C and printing temperatures as 155°C & 170°C for LDPE and HDPE respectively. 9 pins (HDPE-TPS Al_2O_3) with composition as HDPE 90% by weight, Al_2O_3 300G 3.33% by weight, Al_2O_3 400G 3.33% by weight and Al_2O_3 500G 3.34% by weight and similarly, 9 pins (LDPE-DPS Al_2O_3) with composition LDPE 50% by weight, Al_2O_3 400G 25% by weight and Al_2O_3 500G 25% by weight have been printed and compared with corresponding pins printed with composition as HDPE (100% by weight) and LDPE (100% by weight) respectively. Three process parameters (with three levels); RPM, load and time have been taken for pin on disk standard experiment and summarized in [Table 4](#) for HDPE and LDPE as per Taguchi L9 orthogonal array.

Pin on disk experiments were carried out as per [Table 4](#) and wear values were observed separately for HDPE and LDPE cases and summarized in [Table 5](#) respectively. Further, initial and final weights of pins have been considered for calculation of weight loss.

Further RT (HDPE-TPS Al_2O_3 and LDPE- DPS Al_2O_3) and work pieces (HDPE and LDPE without any reinforcement) have been printed on FDM setup as per input parameters considered under Taguchi L9 technique. The printing temperature used for 3D printing of TPS reinforced HDPE RT was $170 \pm 5^\circ C$ and DPS reinforced LDPE RT was $155 \pm 5^\circ C$. The three process parameters (Infill Density, Infill angle, Infill speed) with three levels were selected for printing as per L9 orthogonal array technique for HDPE and LDPE RT as shown in [Table 6](#).

Further, Shore-D hardness and dimensional accuracy (in terms of Deviation in width i.e., Deviation X and Deviation in length i.e., Deviation Y) of HDPE and LDPE RT have been checked and summarized in [Table 7](#).

The RT prepared (both HDPE and LDPE) have been put to machining against work pieces (circular discs) on vertical milling machine as per L9 Taguchi orthogonal array with three input parameters (speed, Feed, depth of cut). Different cases have been considered to determine tool life and machinability of RT and work pieces.

Case 1: LDPE (100% composition) as work piece (WP) and HDPE - TPS Al_2O_3 (HDPE as 90% by weight, Al_2O_3 -300G as 3.33% by weight, Al_2O_3 -400G as 3.33% by weight, Al_2O_3 -500G as 3.33% by weight) as tooling.

In case 1, 09 work pieces of LDPE (100% by weight) and 09 RT of HDPE - TPS Al_2O_3 (HDPE as 90% by weight, Al_2O_3 -300G as 3.33% by weight, Al_2O_3 -400G as 3.33% by weight, Al_2O_3 -500G as 3.33% by weight) have been taken.

Table 3 Output parameters (mechanical properties) computed using UTT for HDPE

Levels	Output parameters (For HDPE)					Output parameters (For LDPE)				
	A	B	C	D	E	A	B	C	D	E
L1	11.8	2.14	10.22	2.04	1.37	9.8	3.04	9.08	2.23	6

Note: Where A is Peak load (N), B is peak elongation (mm), C is Break load (N), D is break elongation (mm), and E is Young's Modulus (MPa).

Bedi, P., Singh, S., Ahuja, I.P.S., 2018. Investigations for Rapid Tooling Prepared With Waste Polymer-Based Hybrid Filament. Reference Module in Materials Science and Materials Engineering. Oxford: Elsevier, 1–18.

Case 2: HDPE (100% composition) as work piece (WP) and LDPE - DPS Al_2O_3 (LDPE 50% by weight, Al_2O_3 -400G 25% by weight, Al_2O_3 -500G 25% by weight) as tooling.

In case 2, 09 work pieces of HDPE (100% by weight) and 09 RT of LDPE - DPS Al_2O_3 (LDPE 50% by weight, Al_2O_3 -400G 25% by weight, Al_2O_3 -500G 25% by weight) have been taken.

Work pieces in both cases have been mounted on the base plate of milling machine (fixed) whereas tooling have been mounted on tool post perpendicular to the work piece and feed has been given horizontally parallel to base plate. Table 8 shows different levels of input parameters considered for machining on vertical milling set up as per Taguchi L9 technique.

Initial and final weights of discs (WP) and RT for both case 1 and case 2 have been noted to compute the weight loss during the machining and summarized in Table 9.

Results and Discussions

Results for Mechanical Properties of Filament Wires

SN ratio analysis has been done for each of the mechanical properties computed as per Taguchi L18 technique separately for HDPE and LDPE filament wires (as per Table 3) and summarized in Table 10.

Various SN plots, variance analysis and ranking tables for all mechanical properties for HDPE and LDPE have been obtained using Minitab 17 software. Fig. 7 shows the SN plots for different mechanical properties of HDPE filament wire. Tables 11 and 12

show analysis of Variance for SN ratios and Signal to noise ratios for different mechanical properties of HDPE filament wire respectively.

After combined optimization, It has been seen that level 3 of composition (HDPE 90% by weight, Al_2O_3 300G 3.33% by weight, Al_2O_3 400G 3.33% by weight and Al_2O_3 500G 3.34% by weight), level 1 of load (5 kgf), level 2 of temperature (190°C) and level 2 of RPM (40) are best settings for HDPE filament wire to have maximum mechanical strength. Further, composition came out to be the major factor contributing (with 51.15% contribution) for maximizing the mechanical strength of HDPE filament wire at 5% level of significance while effect of other parameters can be ignored as their p-value is coming more than 0.05.

Fig. 8 shows the SN plots for different mechanical properties of LDPE filament wire. Tables 13 and 14 show analysis of Variance for SN ratios and Signal to noise ratios for different mechanical properties of LDPE filament wire respectively.

Fig. 7 SN plots for different mechanical properties of HDPE filament wire.

Results for Pin on Disk Experimentation of Pins Printed

SN ratio analysis has been done for wear of the pins printed on FDM as per Table 4. SN ratios (for smaller the better type case) for wear for pure HDPE, HDPE TPS Al_2O_3 , pure LDPE and LDPE DPS Al_2O_3 pins have been summarized in Table 15. Fig. 9 shows the SN plots for wear for pure HDPE, HDPE TPS Al_2O_3 , pure LDPE and LDPE DPS Al_2O_3 pins. Tables 16 and 17 shows variance analysis and response table for SN ratios for wear of pure HDPE, HDPE TPS Al_2O_3 , pure LDPE and LDPE DPS Al_2O_3 pins.

It has been seen that level 1 of rpm (250), level 1 of load (1 kgf), level 3 of time (15 min) are best settings for pure HDPE pin to have minimum wear. Further, load came out to be major factor contributing (with 70.63% contribution) for minimizing the wear of pure HDPE pin at 5% level of significance.

It has been seen that level 1 of rpm (250), level 1 of load (1 kgf), level 3 of time (15 min) are best settings for HDPE TPS Al_2O_3 pin to have minimum wear. Further, load came out to be major factor contributing (with 69.31% contribution) for minimizing the wear of HDPE TPS Al_2O_3 pin at 5% level of significance.

It has been seen that level 1 of rpm (250), level 1 of load (1 kgf), level 3 of time (15 min) are best settings for pure LDPE pin to have minimum wear. Further, load came out to be major factor contributing (with 71.36% contribution) for minimizing the wear of pure LDPE pin at 5% level of significance.

It has been seen that level 1 of rpm (250), level 1 of load (1 kgf), and level 3 of time (15 min) are best settings for LDPE DPS Al_2O_3 pin to have minimum wear. Further, load came out to be major factor contributing (with 74.18% contribution) for minimizing the wear of LDPE DPS Al_2O_3 pin at 5% level of significance.

The wear tracks for HDPE and LDPE pins (L1–L9 have been shown in Fig. 10, which clearly highlights the extent of wear on pins, when rubbed against the disk.

It has been observed that wear tracks for pure HDPE pin and pure LDPE pin were quite sharper than that of tracks for reinforced HDPE and LDPE pins which clearly indicates that wear decreases when HDPE gets reinforced with TPS Al₂O₃ reinforcement and LDPE gets reinforced with DPS Al₂O₃ reinforcement.

Fig. 8 SN plots for different mechanical properties of LDPE filament wire.

Results for RT Prepared

SN ratio analysis for dimensional accuracy (Deviation X and Deviation Y) and shore D hardness has been done for RT printed on FDM as per table 4.6. SN ratios for dimensional accuracy and hardness for HDPE TPS Al_2O_3 RT and LDPE DPS Al_2O_3 RT has been summarized in Table 18. Fig. 11 shows SN plots for dimensional accuracy in width and length (Deviation X and Deviation Y) and Shore-D hardness of HDPE and LDPE RT. Tables 19 and 20 shows variance analysis and response table for various HDPE and LDPE RT.

It has been seen that level 2 of infill density (80%), level 2 of infill angle (60°), level 3 of infill speed (60 mm/s) are best settings for pure HDPE TPS Al_2O_3 RT to have maximum dimensional accuracy in width (Deviation X) of HDPE TPS Al_2O_3 RT. Further, infill density came out to be major factor contributing (with 98.05% contribution) for maximizing the dimensional accuracy in width (Deviation X) of HDPE TPS Al_2O_3 RT at 5% level of significance.

It has been seen that level 1 of infill density (60%), level 1 of infill angle (45°), level 2 of infill speed (50 mm/s) are best settings for pure HDPE TPS Al_2O_3 RT to have maximum dimensional accuracy in length (Deviation Y) of HDPE TPS Al_2O_3 RT. Further, infill angle came out to be major factor contributing (with 50.08% contribution) for maximizing the dimensional accuracy in width (Deviation Y) of HDPE TPS Al_2O_3 RT at 5% level of significance.

It has been seen that level 2 of infill density (80%), level 3 of infill angle (75°), level 3 of infill speed (60 mm/s) are best settings for pure HDPE TPS Al_2O_3 RT to have maximum shore D hardness of HDPE TPS Al_2O_3 RT. Further, infill density came out to be

7	12.3958	10.4576	34.9638
8	12.0412	10.1728	35.1175
9	10.7520	9.8970	35.1934
LDPE DPS Al ₂ O ₃ RT.			
1	11.0568	9.1186	32.7698
2	11.3727	10.7520	33.0643
3	16.4782	12.3958	33.2552
4	10.7520	7.7443	32.5678
5	13.1515	11.0568	32.8691
6	18.4164	13.1515	33.2552
7	9.8970	8.4043	32.6694
8	14.4249	10.7520	32.9672
9	16.4782	11.7005	33.0643

Note: (It should be noted that "smaller the better" case is considered for SN values for deviation X and deviation Y and "larger the better" case is considered for SN values of Shore D hardness).

major factor contributing (with 65.35% contribution) for maximizing the shore D hardness of HDPE TPS Al₂O₃ RT at 5% level of significance.

It has been seen that level 2 of infill density (80%), level 3 of infill angle (75°), level 1 of infill speed (40 mm/s) are best settings for pure LDPE DPS Al₂O₃RT to have maximum dimensional accuracy in width (Deviation X). Further, infill angle came out to be major factor contributing (with 89.27% contribution) for maximizing the dimensional accuracy in width (Deviation X) of LDPE DPS Al₂O₃ RT at 5% level of significance.

It has been seen that level 1 of infill density (60%), level 3 of infill angle (75°), level 1 of infill speed (40 mm/s) are best settings for pure LDPE DPS Al₂O₃RT to have maximum dimensional accuracy in length (Deviation Y). Further, infill angle came out to be major factor contributing (with 92.18% contribution) for maximizing the dimensional accuracy in length (Deviation Y) of LDPE DPS Al₂O₃ RT at 5% level of significance.

It has been seen that level 1 of infill density (60%), level 3 of infill angle (75°), level 1 of infill speed (40 mm/s) are best settings for pure LDPE DPS Al₂O₃RT to have maximum shore D hardness of LDPE DPS Al₂O₃ RT. Further, infill angle came out to be major factor contributing (with 86.61% contribution) for maximizing the shore D hardness of LDPE DPS Al₂O₃ RT at 5% level of significance.

Further, from [Table 7](#), it has been seen that printed width and length for HDPE tooling printed as per level L5 is 10.15 and 35.31 respectively. Similarly, it has been seen that printed width and length for LDPE tooling printed as per level L5 is 10.32 and 35.38.

[Table 21](#) shows values for width and length of HDPE and LDPE RT printed repeatedly as per the best level specified before. Process capability analysis has been carried out for dimensional accuracy of HDPE TPS Al₂O₃ tooling and LDPE DPS Al₂O₃RT at best settings and summarized in [Table 22](#).

SN ratio analysis has been done for weight loss of WP (machinability) and weight loss for RT (tool life) while machining on vertical milling machine as per [Table 8](#). SN ratios for weight losses of WP and RT for case 1 and case 2 are summarized in [Table 23](#). [Fig. 12](#) shows SN plots for HDPE and LDPE RT. [Tables 24](#) and [25](#) shows variance analysis and response table for SN ratios respectively for HDPE and LDPE RT.

After combined optimization, it has been seen that level 1 of speed (500 rpm), level 3 of feed (40 mm/min), level 1 of depth of cut (1 mm) are best settings for maximizing the machinability of LDPE WP and tool life of HDPE TPS Al₂O₃ RT as per case 1. Further, feed came out to be major factor contributing (with 93.79% contribution) for maximizing the machinability of WP and tool life of RT under case 1 at 5% level of significance.

Similarly, after combined optimization, it has been seen that level 3 of speed (1000 rpm), level 3 of feed (40 mm/min), level 2 of depth of cut (2 mm) for maximizing the machinability of HDPE WP and tool life of LDPE DPS Al₂O₃ RT as per case 2. Further, feed came out to be major factor contributing (with 71.51% contribution) for maximizing the machinability of WP and tool life of RT under case 2 at 5% level of significance.

Further, Shore-D hardness and porosity of WP and RT has been checked for both cases. [Table 26](#) shows hardness and porosity of WP and RT for both case 1 and case 2.

HDPE TPS Al₂O₃RT.LDPE DPS Al₂O₃RT.

Fig. 11 SN plots for dimensional accuracy in width and length (Deviation X and Deviation Y) and Shore-D hardness of HDPE and LDPE RT.

Zone B (machined portion) of WP and RT for case 1 and case 2 has been examined through optical microscope by support of software tool known as “Metallurgical Image Analysis Software (MIAS)”. Fig. 13 shows the optical micrographs at 100x along with the porosity values for all the WP and RT for case 1 and case 2.

Further, thermal analysis of WP and RT with the best tool life prepared under case 1 and case 2 has been performed for comparing both un-machined (zone A) and machined (zone B) portions by using DSC technique on Mettler Toledo- DSC setup. The thermal plots for WP and RT prepared under best settings as per combined optimization for case 1 and case 2 has been shown in Figs. 14 and 15 respectively. Repetitions had been necessary to eliminate any sort of effect arisen due to contamination and pre

Table 23 SN ratios for weight losses of WP and RT for case 1 and case 2

	CASE 1		CASE 2	
	SN ratios for weight loss of WP	SN ratios for weight loss of RT	SN ratios for weight loss of WP	SN ratios for weight loss of RT
Level 1	− 5.12980	33.5556	− 14.6097	6.70716
Level 2	− 2.82926	31.0568	− 12.9950	6.16070
Level 3	0.28201	26.7448	− 12.1813	5.02074
Level 4	− 5.16122	32.3958	− 14.7986	6.76375
Level 5	− 2.54522	29.3704	− 12.1813	6.21382
Level 6	0.34901	28.1787	− 11.0879	4.82176
Level 7	− 4.97442	31.0568	− 14.3340	7.39144
Level 8	− 2.60364	28.4043	− 13.6387	6.33906
Level 9	0.45681	26.5580	− 10.0614	4.85208

Note: (It should be noted that “larger the better” case is considered for SN values for weight loss for WP, “smaller the better” case is considered for SN values for weight loss for RT and “larger the better” case is considered for SN values for combined optimization for both case 1 and case 2).

stored history. It has been judged from thermal plots, enthalpy values for machined portions (zone B) for both the WP and RT (both cases) came out to be higher than that of un-machined portions (zone A) giving a clear idea that machined portion becomes more thermally stable than that of un-machined portion.

Conclusions

In this study, conclusions drawn at each stage/process are categorized as following:

Process Parametric Optimization for Twin Screw Extruder

- It has been seen that level 3 of composition (HDPE 90% by weight, Al₂O₃ 300G 3.33% by weight, Al₂O₃ 400G 3.33% by weight and Al₂O₃ 500G 3.34% by weight), level 3 of load (15 kgf), level 2 of temperature (190°C) and level 3 of RPM (45) came out to be best settings for HDPE filament wire to bear the maximum peak load. Further, composition came out to be the major factor contributing (with 74.69% contribution) for maximizing the peak load of HDPE filament wire at 5% level of significance.
- It has been seen that level 3 of composition (HDPE 90% by weight, Al₂O₃ 300G 3.33% by weight, Al₂O₃ 400G 3.33% by weight and Al₂O₃ 500G 3.34% by weight), level 3 of load (15 kgf), level 2 of temperature (190°C) and level 3 of RPM (45) are best settings for HDPE filament wire to have maximum peak elongation. Further, temperature came out to be the major factor contributing (with 38.92% contribution) for maximizing the peak elongation of HDPE filament wire at 5% level of significance.
- It has been seen that level 3 of composition (HDPE 90% by weight, Al₂O₃ 300G 3.33% by weight, Al₂O₃ 400G 3.33% by weight and Al₂O₃ 500G 3.34% by weight), level 3 of load (15 kgf), level 2 of temperature (190°C) and level 3 of RPM (45) are best settings for HDPE filament wire to bear the maximum break load. Further, composition came out to be the major factor contributing (with 74.95% contribution) for maximizing the break load of HDPE filament wire at 5% level of significance.
- It has been seen that level 3 of composition (HDPE 90% by weight, Al₂O₃ 300G 3.33% by weight, Al₂O₃ 400G 3.33% by weight and Al₂O₃ 500G 3.34% by weight), level 3 of load (15 kgf), level 2 of temperature (190°C) and level 3 of RPM (45) are best settings for HDPE filament wire to have maximum break elongation. Further, temperature came out to be the major factor contributing (with 41.27% contribution) for maximizing the break elongation of HDPE filament wire at 5% level of significance.
- It has been seen that level 2 of composition (HDPE 50% by weight, Al₂O₃ 400G 25% by weight and Al₂O₃ 500G 25% by weight), level 2 of load (10 kgf), level 2 of temperature (190°C) and level 2 of RPM (40) are best settings for HDPE filament wire to have maximum Young's Modulus. Further, composition came out to be the major factor contributing (with 75.94% contribution) for maximizing the Young's modulus of HDPE filament wire at 5% level of significance.

After combined optimization, It has been seen that level 3 of composition (HDPE 90% by weight, Al₂O₃ 300G 3.33% by weight, Al₂O₃ 400G 3.33% by weight and Al₂O₃ 500G 3.34% by weight), level 1 of load (5 kgf), level 2 of temperature (190°C) and level 2 of RPM (40) are best settings for HDPE filament wire to have maximum mechanical strength. Further, composition came out to be the major factor contributing (with 51.15% contribution) for maximizing the mechanical strength of HDPE filament wire at 5% level of significance while effect of other parameters can be ignored as their p-value is coming more than 0.05.

Combined optimization (case 2)		
Rank 2	1	3

- It has been seen that level 2 of composition (LDPE 50% by weight, Al₂O₃ 400G 25% by weight and Al₂O₃ 500G 25% by weight), level 3 of load (15 kgf), level 1 of temperature (185°C) and level 1 of RPM (35) are best settings for LDPE filament wire to bear the maximum peak load. Further, composition came out to be major factor contributing (with 90.26% contribution) for maximizing the peak load of LDPE filament wire at 5% level of significance.
- It has been seen that level 1 of composition (LDPE 50% by weight, and Al₂O₃ 500G 50% by weight), level 3 of load (15 kgf), level 2 of temperature (190°C) and level 3 of RPM (45) are best settings for LDPE filament wire to have maximum peak elongation. Further, load came out to be major factor contributing (with 56.98% contribution) for maximizing the peak elongation of LDPE filament wire at 5% level of significance.
- It has been seen that level 2 of composition (LDPE 50% by weight, Al₂O₃ 400G 25% by weight and Al₂O₃ 500G 25% by weight), level 3 of load (15 kgf), level 1 of temperature (185°C) and level 1 of RPM (35) are best settings for LDPE filament wire to bear the maximum break load. Further, composition came out to be major factor contributing (with 88.51% contribution) for maximizing the break load of LDPE filament wire at 5% level of significance.
- It has been seen that level 1 of composition (LDPE 50% by weight, and Al₂O₃ 500G 50% by weight), level 3 of load (15 kgf), level 2 of temperature (190°C) and level 3 of RPM (45) are best settings for LDPE filament wire to have maximum break elongation. Further, load came out to be major factor contributing (with 64.99% contribution) for maximizing the break elongation of LDPE filament wire at 5% level of significance.
- It has been seen that level 2 of composition (LDPE 50% by weight, Al₂O₃ 400G 25% by weight and Al₂O₃ 500G 25% by weight), level 3 of load (15 kgf), level 2 of temperature (190°C) and level 2 of RPM (40) are best settings for LDPE filament wire to have maximum Young's Modulus. Further, composition came out to be major factor contributing (with 91.88% contribution) for maximizing the Young's modulus of LDPE filament wire at 5% level of significance.

After combined optimization, it has been seen that level 3 of composition (LDPE 50% by weight, Al₂O₃ 400G 25% by weight and Al₂O₃ 500G 25% by weight), level 3 of load (15 kgf), level 2 of temperature (190°C) and level 1 of RPM (35) are best settings for LDPE filament wire to have maximum mechanical strength. Further, composition came out to be the major factor contributing (with 42.13% contribution) for maximizing the mechanical strength of LDPE filament wire at 5% level of significance while effect of other parameters can be ignored as their p-value is coming more than 0.05

Process Parametric Optimization for Pin on Disk Experimentation

- It has been seen that level 1 of rpm (250), level 1 of load (1 kgf), level 3 of time (15 min) are best settings for pure HDPE pin to have minimum wear. Further, load came out to be major factor contributing (with 70.63% contribution) for minimizing the wear of pure HDPE pin at 5% level of significance.
- It has been seen that level 1 of rpm (250), level 1 of load (1 kgf), level 3 of time (15 min) are best settings for HDPE TPS Al₂O₃ pin to have minimum wear. Further, load came out to be major factor contributing (with 69.31% contribution) for minimizing the wear of HDPE TPS Al₂O₃ pin at 5% level of significance.
- It has been seen that level 1 of rpm (250), level 1 of load (1 kgf), level 3 of time (15 min) are best settings for pure LDPE pin to have minimum wear. Further, load came out to be major factor contributing (with 71.36% contribution) for minimizing the wear of pure LDPE pin at 5% level of significance.
- It has been seen that level 1 of rpm (250), level 1 of load (1 kgf), and level 3 of time (15 min) are best settings for LDPE DPS Al₂O₃ pin to have minimum wear. Further, load came out to be major factor contributing (with 74.18% contribution) for minimizing the wear of LDPE DPS Al₂O₃ pin at 5% level of significance.

Table 26 Hardness and porosity values for WP and RT for both case 1 and case 2

		WP				RT					
			Hardness for Zone A	Hardness for Zone B	Porosity before machining (%)	Porosity after machining (%)		Hardness for Zone A	Hardness for Zone B	Porosity before machining (%)	Porosity after machining (%)
Case 1	Level 1	LDPE	39.5	43	7.41	3.12	HDPE reinforced	71.5	80.5	30.21	15.48
	Level 2		40	46		3.94		74.5	81.5		14.21
	Level 3		42.5	41.5		7.48		74.5	81		24.23
	Level 4		41.5	40		3.22		73.5	78		14.58
	Level 5		40.5	46.5		4.29		77.5	80		17.66
	Level 6		42	47.5		7.81		74	81.5		16.98
	Level 7		40	44.5		3.47		76	80		14.34
	Level 8		39.5	41		4.78		72.5	83.5		17.97
	Level 9		40	46		8.42		77	87.5		22.42
Case 2	Level 1	HDPE	56.5	61.5	15.54	8.47	LDPE reinforced	44.5	50.5	22.79	13.47
	Level 2		58.5	64.5		12.49		48.5	58.5		14.54
	Level 3		57	62		10.22		48	52.5		15.49
	Level 4		56	67		9.64		45	57.5		14.41
	Level 5		56.5	68		11.49		43.5	55		16.74
	Level 6		57.5	64		12.09		45.5	56		18.49
	Level 7		56.5	65.5		9.43		48	55.5		15.42
	Level 8		58	61.5		10.69		50.5	58		16.57
	Level 9		59.5	63		14.57		48	52.5		19.54

Fig. 13 Optical micrographs of WP and RT after machining (Zone B) (Case 1 and Case 2).

- It has been observed that wear tracks for pure HDPE pin and pure LDPE pin were quite sharper than that of tracks TPS based HDPE pins and DPS based LDPE pins which clearly indicates that wear decreases when HDPE gets reinforced with TPS Al_2O_3 reinforcement and LDPE gets reinforced with DPS Al_2O_3 reinforcement.

Process Parametric Optimization for Fused Deposition Modeling (FDM)

- It has been seen that level 2 of infill density (80%), level 2 of infill angle (60°), level 3 of infill speed (60 mm/s) are best settings for pure HDPE TPS Al_2O_3 RT to have maximum dimensional accuracy in width (Deviation X) of HDPE TPS Al_2O_3 RT. Further,

Fig. 14 Thermal plots for WP and RT prepared under best settings as per combined optimization for case 1.

infill density came out to be major factor contributing (with 98.05% contribution) for maximizing the dimensional accuracy in width (Deviation X) of HDPE TPS Al₂O₃ RT at 5% level of significance.

- It has been seen that level 1 of infill density (60%), level 1 of infill angle (45°), level 2 of infill speed (50 mm/s) are best settings for pure HDPE TPS Al₂O₃ RT to have maximum dimensional accuracy in length (Deviation Y) of HDPE TPS Al₂O₃ RT. Further, infill angle came out to be major factor contributing (with 50.08% contribution) for maximizing the dimensional accuracy in width (Deviation Y) of HDPE TPS Al₂O₃ RT at 5% level of significance.

After combined optimization, it has been seen that level 2 of infill density (80%), level 1 of infill angle (45°), level 1 of infill speed (40 mm/s) are best settings for HDPE TPS Al₂O₃ RT to have maximum dimensional accuracy (both in terms of width and length) of HDPE TPS Al₂O₃ RT. Further, infill density came out to be major factor contributing (with 94.94% contribution) for maximizing the dimensional accuracy in width and length (Deviation X and Deviation Y) of HDPE TPS Al₂O₃ RT at 5% level of significance.

- It has been seen that level 2 of infill density (80%), level 3 of infill angle (75°), level 3 of infill speed (60 mm/s) are best settings for pure HDPE TPS Al₂O₃ RT to have maximum shore D hardness of HDPE TPS Al₂O₃ toolings. Further, infill density came out to be major factor contributing (with 65.35% contribution) for maximizing the shore D hardness of HDPE TPS Al₂O₃ RT at 5% level of significance.

Fig. 15 Thermal plots for WP and RT prepared under best settings as per combined optimization for case 2.

- It has been seen that level 2 of infill density (80%), level 3 of infill angle (75°), level 1 of infill speed (40 mm/s) are best settings for pure LDPE DPS Al_2O_3 RT to have maximum dimensional accuracy in width (Deviation X). Further, infill angle came out to be major factor contributing (with 89.27% contribution) for maximizing the dimensional accuracy in width (Deviation X) of LDPE DPS Al_2O_3 RT at 5% level of significance.
- It has been seen that level 1 of infill density (60%), level 3 of infill angle (75°), level 1 of infill speed (40 mm/s) are best settings for pure LDPE DPS Al_2O_3 RT to have maximum dimensional accuracy in length (Deviation Y). Further, infill angle came out to be major factor contributing (with 92.18% contribution) for maximizing the dimensional accuracy in length (Deviation Y) of LDPE DPS Al_2O_3 RT at 5% level of significance.

After combined optimization, it has been seen that level 1 of infill density (60%), level 1 of infill angle (45°), level 2 of infill speed (50 mm/s) are best settings for LDPE DPS Al_2O_3 RT to have maximum dimensional accuracy (both in terms of width and length). Further, infill angle came out to be major factor contributing (with 92.00% contribution) for maximizing the dimensional accuracy in width and length (Deviation X and Deviation Y) of LDPE DPS Al_2O_3 RT at 5% level of significance.

- It has been seen that level 1 of infill density (60%), level 3 of infill angle (75°), level 1 of infill speed (40 mm/s) are best settings for pure LDPE DPS Al_2O_3 RT to have maximum shore D hardness of LDPE DPS Al_2O_3 RT. Further, infill angle came out to be major factor contributing (with 86.61% contribution) for maximizing the shore D hardness of LDPE DPS Al_2O_3 RT at 5% level of significance.

Process Capability Analysis

- The process capability analysis for dimensional accuracy (in terms of width) of HDPE TPS Al_2O_3 tooling has been done and values for C_p and C_{pk} came out to be 1.586 and 1.359 respectively (i.e., > 1.33) which clearly indicate that HDPE TPS Al_2O_3 tooling is dimensionally accurate (in terms of width).
- The process capability analysis for dimensional accuracy (in terms of length) of HDPE TPS Al_2O_3 tooling has been done and values for C_p and C_{pk} came out to be 1.538 and 1.391 respectively (i.e., > 1.33) which clearly indicate that HDPE TPS Al_2O_3 tooling is dimensionally accurate (in terms of length).
- The process capability analysis for dimensional accuracy (in terms of width) of LDPE DPS Al_2O_3 tooling has been done and values for C_p and C_{pk} came out to be 1.511 and 1.375 respectively (i.e., > 1.33) which clearly indicate that LDPE DPS Al_2O_3 tooling is dimensionally accurate (in terms of width).
- The process capability analysis for dimensional accuracy (in terms of length) of LDPE DPS Al_2O_3 tooling has been done and values for C_p and C_{pk} came out to be 1.476 and 1.383 respectively (i.e., > 1.33) which clearly indicate that LDPE DPS Al_2O_3 tooling is dimensionally accurate (in terms of length).

Process Parametric Optimization for Vertical Milling Machine

- It has been seen that level 3 of speed (1000 rpm), level 3 of feed (40 mm/min), level 3 of depth of cut (3 mm) are best settings for maximizing the weight loss (thus maximizing the machining) of pure LDPE WP. Further, feed came out to be major factor contributing (with 99.82% contribution) for maximizing the weight loss (thus maximizing the machining) of WP under case 1 at 5% level of significance.
- It has been seen that level 1 of speed (500 rpm), level 1 of feed (20 mm/min), level 1 of depth of cut (1 mm) are best settings for minimizing the weight loss (thus maximizing the tool life) of HDPE TPS Al_2O_3 tooling. Further, feed came out to be major factor contributing (with 82.88% contribution) for minimizing the weight loss (thus maximizing the tool life) of RT under case 1 at 5% level of significance.

After combined optimization, it has been seen that level 1 of speed (500 rpm), level 3 of feed (40 mm/min), level 1 of depth of cut (1 mm) are best settings for maximizing the machinability of LDPE WP and tool life of HDPE TPS Al_2O_3 RT as per case 1. Further, feed came out to be major factor contributing (with 93.79% contribution) for maximizing the machinability of WP and tool life of RT under case 1 at 5% level of significance.

- It has been seen that level 3 of speed (1000 rpm), level 3 of feed (40 mm/min), level 2 of depth of cut (2 mm) are best settings for maximizing the weight loss (thus maximizing the machining) of pure HDPE WP. Further, feed came out to be major factor contributing (with 84.08% contribution) for maximizing the weight loss (thus maximizing the machining) of WP under case 2 at 5% level of significance.
- It has been seen that level 3 of speed (1000 rpm), level 1 of feed (20 mm/min), level 3 of depth of cut (3 mm) are best settings for minimizing the weight loss (thus maximizing the tool life) of LDPE DPS Al_2O_3 tooling. Further, feed came out to be major factor contributing (with 95.22% contribution) for minimizing the weight loss (thus maximizing the tool life) of RT under case 2 at 5% level of significance.

After combined optimization, it was seen that level 3 of speed (1000 rpm), level 3 of feed (40 mm/min), level 2 of depth of cut (2 mm) for maximizing the machinability of HDPE WP and tool life of LDPE DPS Al_2O_3 RT as per case 2. Further, feed came out to be major factor contributing (with 71.51% contribution) for maximizing the machinability of WP and tool life of RT under case 2 at 5% level of significance.

Limitations and Future Scope of the Study

- In the present study, use of single reinforcement ($\text{SiC}/\text{Al}_2\text{O}_3$) has been studied. Further, study may be extended by using hybrid reinforcements like $\text{SiC} + \text{Al}_2\text{O}_3$ in different proportions.
- In the present study, HDPE and LDPE has been used as matrix material (as commercially, HDPE and LDPE constitute major portion of polymer waste) for printing of RT. Other waste polymer materials like acrylonitrile butadiene styrene (ABS), polylactic acid (PLA) etc. may be explored as matrix material for printing of RT.
- In the present study, thermoplastic materials have been used in printing applications. Till now, no work has been reported on use of thermosets as filler material in printing applications. Further, study may be conducted to use thermosets as reinforcement in thermoplastic matrix.
- In the present study, machining with RT on vertical milling has been explored. Further, studies may be performed for turning, drilling etc., along with their parametric optimization.
- In the present study, layers of same material (HDPE/LDPE) have been printed on FDM. In future studies, multi-material printing may be explored for tool life.
- In the present study, thermal analysis of RT has been done. Further, dynamic analysis may be done to calculate loss modulus/storage modulus.

Introduction

Laser cutting in general is an effective way to reduce production and manufacturing costs. This is due to the advantage of high production rates as well as the fact that lasers can be mechanized, computer controlled, and integrated into assembly lines. Many industries have been revolutionized by the application of laser equipment in their production lines. This is because of the high-quality and low distortion characteristics of the cutting action that can be achieved. Most materials can be cut by the process including metals, wood, plastics, rubber, composites, etc. On the other hand, some materials cannot be cut by this process due to safety reasons (Powell, 1998). GFRP, sometimes known as glass fiber-reinforced polymer (GFRP), is one of the materials that can be cut using a CO₂ laser beam. This composite material has been used for many decades for all engineering applications including the automotive, marine, and construction industries (Sathishkumar *et al.*, 2014; Masuelli, 2013). GFRP has several advantages including high strength to weight ratio, high fracture toughness, and excellent corrosion and thermal resistances. Currently, GFRP has become an economical alternative to other materials in highly corrosive industrial applications. Furthermore, ongoing research has ensured that GFRP now has a combination of properties such as high specific strength, high specific stiffness, and light weight, which makes it attractive for aircraft and aerospace applications. Actually, GFRP is a promising material for many other applications, including boats, automobiles, water tanks, roofing, and pipes (Eltawahni, 2011; Palanikumar, 2007).

Laser cutting of GFRP has attracted many authors (Di Illio *et al.*, 1990; Zhou and Mahdavian, 2004; Nuss, 1988; Tagliaferri *et al.*, 1985; Caprino and Tagliaferri, 1988; Caprino *et al.*, 1995a,b; Cenna and Mathew, 2002; Goeke and Emmelmann, 2010; Riveiro *et al.*, 2007; Dilio and Tagliaferri, 1989; Bamforth *et al.*, 2006). Di Illio *et al.* (1990) have studied the laser cutting of aramid fiber-reinforced plastics. They discussed the effect of process parameters on the quality of the laser cut. They succeeded in presenting a new method of digital image processing for evaluating the cut quality. Zhou and Mahdavian (2004) have discussed the capability of a low power CO₂ laser in cutting various nonmetallic materials including plastics. They developed a theoretical model to estimate the depth of cut that can be achieved if the material properties and cutting speed are known. It was found that the theoretical model agrees with the experimental cutting results. It was mentioned that this development will assist those in the manufacturing industries to choose a suitable laser system for cutting or marking nonmetallic materials. Also, it was demonstrated that a 60 W laser power can be used for cutting nonmetallic materials and is suitable for plastic board cutting. Finally, it was concluded that the deeper the cutting depth, the more energy is required. CO₂ laser cutting of reinforced plastic mold parts has been carried out and the cutting results have been compared with other cutting techniques, such as water jet cutting, milling punching, sawing, using a conventional knife, and using an ultrasonic excited knife. This work was carried out by Nuss (1988). It was shown that laser cutting is faster and cleaner and reduces the time spent on postoperation work. The laser cutting of composites of aramide, graphite, and glass cloth-reinforced polyester have been studied by Tagliaferri *et al.* (1985). They examined the morphology of the cut surfaces by scanning electron microscopy. It was found that the thermal properties of the fibers and matrix are the principal factors that affect cutting performance. It was concluded that the quality of the cut surfaces depends on the type of composite being cut.

Caprino and Tagliaferri (1988) have proposed a simple analytical model to predict the kerf depth and optimal working conditions. It was confirmed that in the laser cutting of carbon reinforced plastic composite materials, the poor quality of the cut surface is due to the difference in the thermal properties of the carbon fiber and the resin matrix. In fact, they observed the best results when laser cutting of aramid fabric reinforced polyester (AFRP) due to the polymeric nature of both of the fiber and matrix. It was reported that their experimental results are in excellent agreement with their theoretical predictions for GFRP, AFRP, and GFRP composites. It was proven that the depth of penetration is linearly correlated with the laser power. In addition, they formulated criteria for the classification of cut quality, based on kerf geometry and HAZ size, to help in selecting the optimum cutting conditions. Caprino *et al.* (1995a) investigated the CO₂ laser cutting of GFRP composites. They introduced an analytical model that allows the depth of kerf to be predicted as a function of the direction of the beam in relation to the direction of travel of the material being worked. They reported a substantial agreement between the experimental results and the theoretical predictions. They stressed the importance of the following when laser cutting of GFRP. This is to characterize the spatial distribution of power of the laser beam and to relate this to the distribution of the fiber in the matrix. The CO₂ laser cutting of glass fiber-reinforced plastic (GFRP) composites has been investigated separately by Caprino *et al.* (1995b). They again proposed an analytical model that allows the depth of the kerf to be predicted. It was found that the theoretical model is in substantial agreement with the experimental results. They developed an equation to determine the influence of the parameters of the material structure on the kerf depth. It was concluded that the optimal cutting conditions are strongly affected by any nonuniform distribution of the fibers across the thickness of the sample. Cenna and Mathew (2002) have presented a

theoretical model that considers the spatial distribution of the laser beam, the interaction time between the laser beam and the workpiece, the absorption coefficient, and thermal properties of the material. They reported a good agreement between their results and the theoretical predictions. It was found that the theoretical model successfully predicts the cut quality parameters such as kerf width, the angle of the cut surfaces, and the transmitted energy loss through the kerf. Moreover, it was suggested that a different material removal mechanism is involved in the laser cutting of GFRP. Finally, it was reported that as the cutting speed increases, the kerf width and the kerf angle decrease.

Goeke and Emmelmann (2010) have investigated the influence of laser cutting parameters on the quality of carbon fiber-reinforced plastic (CFRP) parts. Their challenge was to apply a CO₂ laser beam and a fiber laser to cut this material and achieve a small heat-affected zone (HAZ). A large HAZ is a result of the large difference between the decomposition temperatures of resin and fiber material (i.e., the decomposition temperature of carbon fiber is about 3000 K and that of epoxy resin is about 550 K). It was found that both the HAZ size and the kerf width decrease significantly with high cutting speeds and small energy inputs. Additionally, they demonstrated that both the CO₂ and the fiber laser beam sources are applicable for the laser beam cutting (LBC) of CFRP forming high-quality parts. However, it was found that when processing CFRP laminates with thickness between 1 and 7 mm the CO₂ laser has an advantage when compared with the fiber laser due to the higher absorption of the 10.6 μm wavelength, by the material. A study of the possibilities of using a high-quality CO₂ laser to cut 3-mm-thick samples of CFRP in plate form was presented by Riveiro *et al.* (2007). They investigated the influence of different processing parameters such as the pulse frequency, the pulse energy, the duty cycle, and type and pressure of the assist gas on the cut quality. They evaluated the quality of the cuts in terms of kerf width, perpendicularity of cut kerf, delaminating degree, and extension of the HAZ. It was reported that an adequate selection of values for the processing parameters allowed good quality cuts to be obtained. The thermal damage caused during laser cutting of aramid fiber/epoxy laminates was investigated by Dilio and Tagliaferri (1989). They examined samples cut with a 500 W CO₂ CW laser using different parameters by both optical and scanning electron microscopy. It was reported that cracks were detected in plies with the fiber direction at 90° to the cutting direction. They developed a model to relate the material damage to the cutting parameters. Bamforth *et al.* (2006) have investigated CO₂ laser cutting of nylon textiles with the aim of optimizing the edge quality. It was reported that nylon textiles can be cut using either a CW or a pulsed CO₂ laser. They optimized the process with the aid of a procedure referred to as 3D finite difference technique. It was mentioned that the edge quality can be significantly better when using the pulsed cutting mode.

If a manufacturer wishes to introduce laser cutting as a technique in any manufacturing process, it is necessary to study the effect of the process on a new material. A number of preferred characteristics such as accuracy of the cut and quality of the surface finish can be specified and also process characteristics such as high speed and low power usage can be also stipulated. It is then necessary to vary the laser input parameters and test whether or not the desired quality features are achieved. This procedure is usually performed by skilled workers. However, this procedure of selection of parameters is based on trial and error and is usually time-consuming. Moreover, the conventional one by one technique is not systematic and usually does not lead to an optimized combination of laser cutting parameters. This is due to the fact that the laser cutting process is affected by complex interactions of the different input and output parameters. A systematic study, based on design of experiment techniques followed by the analysis of the results using response surface methodology (RSM), will allow the detection and visualization of the interactive effects of the input parameters on the results. Once a study of this kind has been done, the optimum combinations of laser cutting parameters can be selected and then used to produce the desired specifications (Eltawahni, 2011). Therefore, it's the aim of this research work to apply RSM, using Box–Behnken design (BBD), to model and optimize the laser cutting process of GFRP and to explore the effect of each parameter on the quality features.

Experimental Procedure

Material

The properties of the GFRP sheet utilized in this research are listed in Table 1. A 3-mm-thick GFRP provided in sheet form with dimensions of 900 × 450 mm was used as a workpiece.

Laser Cutting

For GFRP, four process parameters were controlled laser power, cutting speed, air pressure and focal point position. Table 2 shows the process input parameters and experimental design levels used for 3-mm-thick GFRP. A conical shape nozzle was used with

Table 4 Operating costs break down when compressed argon is used

Element of cost	Calculations	Cutting cost, €/h
Laser electrical power	$(20.88 \text{ kVA})(0.8 \text{ pf})(\text{€}0.12359/\text{kWh}) \times (P/1.5)$	$1.376 \times P$
Chiller electrical power	$(11.52 \text{ kVA})(0.8 \text{ pf})(\text{€}0.12359/\text{kWh})$	1.139
Motion controller power	$(4.8 \text{ kVA})(0.8 \text{ pf})(\text{€}0.12359/\text{kWh})$	0.475
Exhaust system power	$(0.9 \text{ kWh})(\text{€}0.12359/\text{kWh})$	0.111
Laser gas LASPUR208	$\{(\text{€}1043.93/\text{bottle})/(\text{1500 l/bottle})\} \times 7.5 \text{ l/72 h}$	0.072
Gas bottle rental	$(\text{€}181.37/720 \text{ h})$	0.252
Chiller additives	$(\text{€}284.80/\text{year})/(8760 \text{ h/year})$	0.033
Compressed argon	$\text{€}12.174 \times 10^{-3}/\text{liter} \times F[\text{l/h}]$	$12.174 \times 10^{-3} \times F$
Nozzle tip	$(\text{€}7.20/200 \text{ h})$	0.036
Exhaust system filters	$(\text{€}5/100 \text{ h})$	0.05
Focus lens	$(\text{€}186/\text{lens})/(1000 \text{ h})$	0.186
Maintenance labor (with overhead)	$(12 \text{ h}/2000 \text{ h operation})(\text{€}50/\text{h})$	0.30
Total operation cost per hour		$2.654 + 1.376 \times P + 12.174 \times 10^{-3} \times F$

nozzle diameter of 1.5 mm and the stand-off distance was maintained at a constant value of 0.5 mm. During the trial cut runs it was found that argon was the most suitable inert gas and leads to good quality cut with less edge burning and minimum HAZ, kerf, and roughness value. Therefore, argon gas was supplied coaxially as an assist gas. Specimens were cut from the panel for each condition in Table 3. Table 3 is a design matrix for four variables using BBD.

Estimation of Operating Cost

Laser cutting operating costs can be estimated as cutting per hour or per unit length. The laser system used in this work utilized CO₂ using a static volume of laser gases of approximately 7.5 l every 72 h. For this laser system with 1.5 kW maximum output power the operating costs generally falls into the categories listed in Table 4. The operating cost calculation does not account for any unscheduled breakdowns and maintenance, such as a breakdown in the table motion controller or PC hard disk replacement. The total approximated operating cost per hour as a function of process parameters can be estimated by $2.654 + 1.376 \times P + 12.174 \times 10^{-5} \times F$. While the total approximated operating cost per unit length of the cut is given by Eq. (1) assuming 85% utilization. Eq. (2) was used to calculate the cutting cost per meter for all samples. At pressure above 1.05 bar the compressed argon will flow in a supersonic manner. Note that these pressure values are independent of nozzle diameter. At pressure value above this threshold the flow rate in [l/h] of these fluids through a nozzle can be easily calculated from Eq. (3) (Eltawahni, 2011).

$$\text{Cutting cost [Euro/m]} = \frac{2.654 + 1.376 \times P [\text{kW}] + 12.174 \times 10^{-3} \times F [l/h]}{(0.85) \times S [\text{mm/min}] [60 \text{min/h}] [m/1000 \text{mm}]} \quad (1)$$

$$\text{cutting cost [Euro/m]} = \frac{2.654 + 1.376 \times P + 12.174 \times 10^{-3} \times F}{0.051 \times S} \quad (2)$$

$$\text{Flow rate [l/h]} = F = 492 \times d^2 (p_g + 1) \quad (3)$$

where:

d : Nozzle diameter [mm].

P_g : Nozzle supply pressure [bar].

Results and Discussion

For this composite material, five responses were successfully measured, namely upper kerf, lower kerf, ratio between upper to lower kerfs, HAZ, and operating cost. The average values of at least three consistent measurements all measured responses are listed in Table 5. The operating cost was estimated using Eq. (2). The estimated operating cost for each experiment is presented in Table 5.

Development of the Mathematical Models

Design-expert software V7 was used to analyze the measured responses. The fit summary output indicates that, for all responses, the quadratic models are statistically recommended for further analysis as they have the maximum predicted and adjusted R^2 (Eltawahni, 2011). The test for significance of the regression models, the test for significance on individual model coefficients, and the lack of fit test were performed using the same statistical package for all responses. By selecting the step-wise regression method, the insignificant model terms can be automatically eliminated. The resulting ANOVA tables (Tables 6–10) for the reduced quadratic models outline the analysis of variance for each response and illustrate the significant model terms. The same tables show also the other adequacy measures R^2 , Adjusted R^2 and Predicted R^2 . All adequacy measures are close to 1, which are in reasonable agreement and indicate adequate models (Eltawahni et al., 2010, 2012). The adequate precision compares the range of the predicted value at the design points to the average prediction error. In all cases the values of adequate precision ratios are significantly greater than 4. An adequate precision ratio above 4 indicates an adequate model (Eltawahni et al., 2011). The developed mathematical models are shown in Eqs. (4)–(8) in terms of actual factors.

Validation of the Developed Models

With the aim of verifying the adequacy of the developed models furthermore, three confirmation experiments were carried out by using new test conditions. These experiments are taken from the optimization results, which are within the investigated range. By using the point prediction option in the software, all the response values can be predicted by substituting these conditions into the previously developed models. **Table 11** presents the experimental conditions, the actual experimental values, the predicted values and the percentage errors. It is clear that all the values of percentage error for all the five responses are in agreement with the values reported in *Benyounis et al. (2008)* and *Olabi et al. (2007)*. Therefore, it would strongly suggest that the models are valid.

Fig. 2 Perturbation plots showing the effect of each factor on the lower kerf for 3-mm-thick glass fiber-reinforced polymer.

Fig. 3 Perturbation plots showing the effect of each factor on the ratio for 3-mm-thick glass fiber-reinforced polymer.

Effect of Process Factors on the Responses

Upper kerf

The results demonstrate that the laser cutting of GFRP is of acceptable quality and depends mainly on the distribution of the fiber along the thickness, which agrees with [Caprino et al. \(1995a\)](#). It is evident from [Fig. 1](#) that the focal point position has the most important significant effect on the upper kerf for GFRP, followed by the cutting speed and the laser power. However, the upper kerf increases as the focal position and cutting speed decrease, while it increases as the laser power increases. These results are in good agreement with the results reported in [Cenna and Mathew \(2002\)](#). The percentage changes in the upper kerf as a result of changing each factor from its lowest value to its highest value while keeping the other factors at their center values are as follows:

Fig. 4 Interaction graph between cutting speed and focal position for 3-mm glass fiber-reinforced polymer.

Fig. 5 Perturbation plots showing the effect of each factor on the ratio for 3-mm-thick glass fiber-reinforced polymer.

Fig. 6 Contours plot showing the effect of laser power and cutting speed on the heat-affected zone for 3-mm-thick glass fiber-reinforced polymer.

(1) changing focal position would result in a decrease of 45.34%; (2) changing the cutting speed would result in a decrease of 16.68%; and (3) changing the laser power would result in an increase of 10.57%. It is obvious that the argon pressure has no significant effect on the upper kerf.

Lower kerf

The perturbation plot for the average lower kerf width for GFRP is presented in Fig. 2. From Fig. 2 it is clear that the laser power is the key factor affecting the lower kerf. The results confirm that the lower kerf decreases as the laser power decreases and this agrees with result found in Cenna and Mathew (2002). When using the highest laser power, the lower kerf is on average 1.51 times wider than that obtained using the lowest laser power. It was found that the cutting speed and focal position have a significant effect on the lower kerf. By using the slowest cutting speed, the lower kerf is on average 1.11 times wider than that obtained using the fastest cutting speed. It is evident that the lower kerf width increases by 1.16 as the focal point position increases from its smallest level to its highest level. However, the air pressure has no significant effect on the average lower kerf for 3-mm-thick GFRP.

Ratio between upper kerf to lower kerf

Fig. 3 demonstrates that the focal position, the laser power, and cutting speed are the LBC parameters that affect the ratio. It was found that the focal position and laser power are the most important factors influencing the ratio. However, the cutting speed only has a minor effect on the ratio. It is clear that as the focal position and laser power increase the ratio would decrease. It is clear from Fig. 3 that a ratio of one is the desirable option to obtain a square cut edge. Fig. 4 is the interaction plot between the cutting speed and focal position. It is evident that at a focal position of -3 mm a ratio of 1.68 could be obtained if the maximum cutting speed of 5000 mm/min was applied. On the other hand, when the focal position is exactly on the surface of the substrate a ratio of 0.77 could be achieved if the slowest cutting speed of 200 mm/min was used. At a focal position of -1.08 mm a ratio of 0.82 might be obtained by using either maximum or minimum cutting speed.

Fig. 7 Contours plot showing the effect of argon pressure and cutting speed on the heat-affected zone for 3-mm-thick glass fiber-reinforced polymer.

Heat-affected zone

For this material the HAZ was successfully modeled. The results indicate that the dimensions of HAZ are between 0.044 and 0.099 mm. [Fig. 5](#) is a perturbation graph showing the effect of the significant laser parameters on this response. It is evident that any increase in the cutting speed and argon pressure would result in smaller HAZ, whereas any increase in the laser power would lead to a larger HAZ. These findings are in agreement with the results reported in [Goeke and Emmelmann \(2010\)](#). The heat input plays an important role in the HAZ extent because as the heat input increases the HAZ becomes wider and vice versa. Therefore, any increase in the laser power results in a wider HAZ, especially at slow cutting speeds. In the case of the argon pressure effect, as mentioned above, the HAZ becomes smaller as the argon pressure increases. This could be related to the cooling effect as the argon pressure increases, which slows down the burning of the cut edge sides, and consequently, leads to a smaller HAZ. [Fig. 6](#) is a contour plot showing the effect of laser power and cutting speed on the HAZ of GFRP. Also, [Fig. 7](#) is a contours plot showing the effect of argon pressure and cutting speed on the HAZ extent of GFRP.

Operating cost

It is evident from the results that the cutting speed, laser power and argon pressure have a strong effect on the operating cost as shown in [Fig. 8](#). However, the laser power and argon pressure have a positive effect on the operating cost and the cutting speed has a negative effect. It is obvious from [Fig. 8](#) and the 3D plots shown in [Fig. 9](#) that the operating cost is more sensitive to the cutting speed than the other factors.

Optimization

Two optimization criteria are presented in [Table 12](#). Each factor and response have been given a specific goal and importance. For this composite material, the measurement of the surface roughness was not possible due to the inconsistency in the

surface roughness values for some specimens and surface roughness values already out of the tester range for some other specimens.

Table 13 shows the optimal laser cutting setting of the process parameters and the matching response values for both criteria for 3-mm GFRP. It is evident that the HAZ extent produced using the optimal setting of the first criterion is on average 13.7% smaller than the one produced by using the optimal setting of the second criterion setting. On the other hand, the cutting operating cost for the second criterion is on average cheaper than that of the first criterion by 10.5%. **Figs. 10** and **11** show green areas, which are the regions that meet the first and second criteria respectively.

Fig. 8 Perturbation plots showing the effect of each factor on the operating cost for 3-mm-thick glass fiber-reinforced polymer.

Fig. 9 3D plots showing the effect of cutting speed and laser power on the operating cost for 3-mm-thick glass fiber-reinforced polymer.

Conclusions

In this study the effect of LBC parameters was determined using mathematical models. The models were developed using Design-Expert software with the aim of assessing the main and interaction effects of the parameters on the quality of the cut section characteristics obtained under the experimental conditions. This contributed to an optimization of the LBC process to produce cuts that fully satisfy the end user requirements. The developed mathematical models and the optimal solutions are applicable within the cutting parameters ranges considered. The conclusions drawn from the study are summarized below:

- (1) The upper kerf increases as the focal position and cutting speed decrease, while it increases as the laser power increases.
- (2) Laser power is the key factor affecting the lower kerf. Also, the cutting speed and focal position have a significant effect on the lower kerf.
- (3) Focal point position and laser power are the most important factors influencing the ratio, with a negative effect. However, the cutting speed only has a minor effect on the ratio.
- (4) Any increase in the cutting speed and argon pressure would result in smaller HAZ, whereas any increase in the laser power would lead to a larger HAZ.
- (5) Cutting speed, laser power, and argon pressure have a strong effect on the operating cost. However, the laser power and argon pressure have a positive effect on the operating cost and the cutting speed has a negative effect.

Introduction

Energy is life. It takes energy to get energy, as life thrives on life. Today, rising energy demand, growing population and climate change are the talk of the town. Mankind eats, consumes, and trades fossil fuels, which will continue to exist for many decades yet the energy transition to low carbon fuels is de rigueur to cope with perilous climate changes (Abas and Khan, 2014). Coal, oil, and gas brought unique economic prosperity, which seems difficult at present, independently with renewable energy sources. Solar and wind energy supply hardly 30% of electricity demand, which is 22% of global energy consumption (Herron *et al.*, 2015). The interesting truth is that the photovoltaic modules, hydrokinetics, and wind turbines themselves are manufactured by using fossil fuels emitting CO₂ in the atmosphere.

Population, economy, and energy are the major drivers of CO₂ emissions worldwide. A population of 7.2 billion is enjoying \$99 trillion gross domestic product (GDP) by using 13 to 14 GTOE fossil fuels and it is predicted that this will rise to 9 billion persons (IEA, 2014a), \$163 trillion GDP and 17 BTOE fossil fuels (BP 2030) by 2030. According to Shell it will increase to 14.9 BTOE by 2035 and 21 BTOE by 2050 (Saththawong *et al.*, 2014a). Annual electricity (23 PWh ~ 545 quadrillion BTU) and fossil fuel demands (14 GTOE) cause 40 GTCO₂/y CO₂ emissions. The current share of renewable sources include 1350 GW hydro, 365 GW wind, 150 GW solar, and 20 GW geothermal energies. Renewable energy sources supply 1856 GW energy. However, this huge contribution is only 20% of global energy demand whereas rest of 80% comes from fossil fuel. The seven sources of fossil fuels contributing to rampant CO₂ emissions include liquid fuels, for example, gasoline (36%), solid fuels like coal (35%), and gaseous fuels such as natural gas (20%), cement production (3%), bunkers (4%), flaring gases (~1%), and nonfuels (<1%) (Raupach *et al.*, 2007).

A rampant rise in fossil fuel consumption is causing rapid climate change, whose economic and ecological consequences will ensue within the lifetime of our teenagers. Worldwide CO₂ emissions were only 11.746 GTCO₂ in the 1970s, 23.485 GTCO₂ in the 1990s, and 29.89 GTCO₂ in the last decade, which later increased to 39 GTCO₂ in 2014. CO₂ emissions due to burning fossil fuels and biomasses are increasing, steadily, at the rate of 630 MtCO₂/y as discussed in our preceding work, shown in Fig. 1.

CO₂ concentration in the air was 280 ppm in 1750, which according to National Oceanic and Atmospheric Administration's (NOAA) keeling curve is 397.36 ppm as of September 2015 (NOAA, 2015). This is the highest level in the last 650,000 years. The natural water-based greenhouse effect had locked the earth's temperature at 14°C for the last 10,000 years; this has increased to 14.7°C in last 265 years, due to H₂O and CO₂ greenhouse effects. Combined H₂O and CO₂ gases' annual greenhouse gas index (AGGI) was 1.30 in 2011, which increased to 1.35 in 2015, thereby increasing the radiative forcing from 2.8 to 3.0 W/m².

The increase in the earth's temperature from 1997 to 2004 (warming period) caused drying of rosewood and acacia trees in Pakistan, which is described in our companion work, and Intergovernmental Panel on Climate Change (IPCC) measures caused a timely hiatus on further rise (Khan *et al.*, 2008). Rise in the earth's average temperature depends on our collective GHG emissions. Proven private and public sector fossil fuel reserves have a potential of 745 and 2795 GtCO₂, respectively, which must remain unused on earth to limit CO₂ below 450 ppm. The greenhouse effect is increasing the earth's temperature as a thermal runaway; a similar effect caused global warming on Venus. Atmospheric compositions of CO₂ and N₂ on Venus are 95.50% and 3.5%, which are opposite to 0.04% and 78% on earth. Climate Armageddon is believed to have happened in prehistoric times, and can happen on earth. Mars has no water yet the presence of 95% CO₂ causes a greenhouse effect, which has increased its temperature from –200 to –58°C.

The IPCC envisaged a policy of GHG emission reduction by increasing carbon capture and sequestration (CCS) rates, and converting CO₂ into fuels, chemicals, and value-added products. The climate change process is geared through growing population, rampant energy demands, and mushrooming economies as depicted in Fig. 2.

We have five decades to increase renewable energy from the current 20% to 50% by 2050 and from 50% to 80% by 2100 to revert global fossil fuels and renewable energy ratios. It is time to convert CO₂ into fuels and value-added products, when derived from the earth's increased concentration of CO₂ in the atmosphere. If we start capturing, storing, using, and converting CO₂ into fuels, chemicals, and building materials, then the energy transition process from conventional fossil fuels to renewable and alternative sources will become easier.

Fossil Fuels, GHGs Emission, and Impact of CO₂

Gases having the ability to trap heat in the atmosphere are called GHG, which include H₂O vapors, CO₂, CH₄, and O₃ with 36%–72%, 9%–26%, 4%–9%, and 3%–7% contributions, respectively. Solar spectrum reaching the earth's surface consists of 5% UV (300–400 nm),

Fig. 1 Global CO₂ emissions and current rate of rise. Reproduced from Abas, N., Kalair, A., Khan, N., 2015. Review of fossil fuels and future energy technologies. *Futures* 69, 31–49. Available at: [doi:10.1016/j.futures.2015.03.003](https://doi.org/10.1016/j.futures.2015.03.003).

Fig. 2 Mitigation of climate change drives by CO₂ utilization.

43% visible (400–700 nm), and 52% NIR (700–2500 nm). The planet earth emits heat at 3.5–80 μm radiations to maintain its thermal equilibrium. Mostly, the earth radiations are absorbed by H₂O and CO₂ in the atmosphere. CO₂ traps 56%, methane 18%, chloro-fluorocarbons (CFCs) 13%, ozone 7%, and nitrous oxide 6% of the sunlight reflected from the earth's surface. Oceans absorb 90% sunshine and ice glaciers reflect 90% of incident light. The earth is steadily warming up at a rate of 0.6 W/m², which is akin to burning kindling under a 71% water filled cauldron (NASA, 2015). F gases are 1% of global GHG emissions but they have global warming potential (GWP), in addition to their ozone depleting effect, than other green gases. Radiative forcing of CO₂ (63%), CH₄ (18.2%), N₂O (6.1%), and F gases (12.6%) are 1.66, 0.48, 0.16, and 6.44 W/m². The lives of some hydrofluorocarbons (HFCs), SF₆, and per-fluorocarbons (PFCs) in the air are 270, 3200, and 50,000 years with a GWP of 11,700, 9200, and 23,900 as compared to 1 for CO₂. Human activities produce CO₂ (74%), CH₄ (14%), N₂O (8%), and fluorinated gases (1%). Annual GHG emissions from various sectors and their corresponding magnitudes of green gases are shown in Table 1 (Barker *et al.*, 2007).

A world community of 7.2 billion persons emits 2.63 GtCO₂/y from their body, which is easily absorbed by nearby trees and lakes. Oil and coal combustions emit CO₂ at the rate of 1.77 GtCO₂/1 Gt of oil and 485 Mt of CO₂/1 Gt of coal. US fossil fuel

Table 1 Global greenhouse gas (GHG) emission sources

Sources (sectors)	Shares (%)	GHGs (%)			
		CO ₂	CH ₄	N ₂ O	F gases
Power	21.3	29.5	0.00	1.10	0.23
Industry	16.8	20.6	0.00	5.90	0.66

Agriculture	12.5	0.00	40.0	62.0	0.00
Proc & Dist	11.3	8.40	29.6	0.00	0.00
Buildings	10.3	12.9	4.8	1.50	0.12
Land use	10.0	9.10	6.6	26.0	0.00
Waste H ₂ O	3.40	0.00	18.1	2.30	0.00
Global GHG% Ave	—	72	18	9	1.1 ^a

^aPercentages of F-gases in British and American GHG emissions were 2.6% and 3% which are being substituted.

consumptions from 1900 to 1999 have already emitted 283.30 Gt of CO₂ and the country's coal, oil, and gas reserves are 121.96 Gt, 694.69 Bb, and 42.3 Btoe with a potentials of 2.5 times more CO₂ emissions. Oil consumption rate was 87 Mb/day in 2008, 110 Mb/day in 2014, and is forecasted to be 120 Mb/day in 2020. Existing global GHG emissions are around 55 GtCO₂-eq/y, which may increase or decrease as is forecasted in [Fig. 3](#).

World oil reserves consist of 30% conventional, 30% oil sands or bitumen, and 25% extra heavy, 15% heavy, and shale oils. EIA expects a world energy mix in 2035 to consist of 29.3% petroleum, 27.2% coal, 22.7% natural gas, 6.7% nuclear, 14.2% renewable, and alternative energy sources ([Abas et al., 2015](#)). Annually, fossil fuel consumptions and land use patterns produce 54 Gt of GHGs out of which 40 Gt is CO₂. The bottom line is our infinite love for finite hydrocarbon honey down to the addiction level. Energy experts have no Holy Grail to provide any substitute for fossil fuels. IPCC energy and environment experts are running a nerve pulling a strenuous race against the clock to cope with climate change.

The Low Carbon Fuels: A Pathway to Grand Energy Transition

Grand energy transition (GET) from fossil fuels to the sustainable, renewable, and alternative energy sources is inevitable to decelerate climate change. GET desires mechanisms, opportunities, and challenges. The major challenges include climate change, population, economy dictating urgency, trade-off, and innovations. Oil, gas, and coal reserves will continue for the next several decades, yet the energy transition to low carbon intensity fuels is necessary to cope with rampant climate change. Globally, investment in the oil and gas sector increased from 2004 to 2011 and started decelerating after 2012.

More than 11,000 papers pointed out the urgency of energy transition to continue modern living standards. Drivers of energy transition are growing population, flooding urbanization, and globalization. More than three megacities are emerging every 4 years. Energy consumption in non-Organisation for Economic Co-operation and Development (OECD) countries surpassed OECD countries in 2005. Coal is fast replacing oil, natural gas liquids (NGL), and feedstock in primary energy ([Araújo, 2014](#)). The energy system is a capital intensive venture that takes \$1600 billion to supply world energy demands today. Worldwide gas fields (3.066 GTOE), oil wells (4.234 GTOE), and coal mines (3.942 GTOE), collectively, supply 13.80 GTOE (80.3%) energy, whereas the rest 2.758 GTOE (19.7%) emanates from a wide range of renewable and alternative energy resources ([Abas et al., 2015](#)). Total primary energy consumption is increasing at the rate of 243 MTOE/y. Global fossil fuels, renewable and alternative energy sources harvested out of esoteric natural energy resources, are shown in [Table 2](#).

We can make the task easier by changing our energy utilization patterns by incorporating renewable sources in our energy mix. We have 1575 EJ (438,000 TWh) solar, 640 EJ (180,000 TWh) wind, 5000 EJ (1,400,000 TWh) geothermal, 276 EJ (77,000 TWh) biomass, 50 EJ (14,000 TWh) hydropower, and 1 EJ (280 TWh) ocean energy sources to replace the fossil fuels, which are on their way toward peaking and depleting in the next few decades.

To make a successful transition from 2014 to 2035 we need more than \$8 trillion in end user efficiency in the residential, transport, and energy sectors and over \$40 trillion on fossil fuels ([IEA, 2014b](#)). Due to low energy-return-on-energy-invested (EROEI) and the oil depletion stories, investors suffer a leverage effect that affects the investment in energy sectors ([Kristoufek, 2014](#)). New global investments in the oil and gas sector have increased from 2004 to 2011 but started declining again after 2012 ([Ellabban et al., 2014](#)). Current status of oil, gas, and coal reserves is shown in [Fig. 4](#).

Annual energy demand of 14 BTOE results in the emission of 40 GtCO₂, which is likely to increase the business as usual to 75 GtCO₂ due to increase of energy demand to 24 to 25 BTOE. Hydro, wind, and solar power sources produce 4, 12, and 46 gCO₂/kWh as compared to 469, 750, and 1001 gCO₂/kWh by gas, oil, and coal, respectively. CCS technology for natural gas, oil, and coal consumption plants will have a positive impact on CO₂ reduction. Underground CO₂ storage seems to be a long-term solution as compared to converting into syngas ([Pau et al., 2010](#)). Coal beds, saline aquifers, salt caverns, and depleted oil and gas reservoirs may be used for CO₂ sequestration as shown in [Fig. 5](#).

CO₂ Utilization Opportunities

Carbon dioxide is perceived as a raw material of the future. Drivers of sustainable CO₂ capture, sequestration, separation and recovery, delivery, purification, and utilization business include conversion of it into energy carriers, fuels, polymers, feedstock; and construction materials, refrigerants, agriculture, artificial photosynthesis, and off-season agriculture. Carbon capture, utilization, and storage (CCUS) technologies mitigate climate change by providing niche business opportunities. Low-carbon green homes, cities, fuels, chemicals, and enhanced fuel recovery systems are recognized as the critical drivers of CO₂ utilization policy. CO₂ may be converted into methane, ethane, carbon monoxide, formic acid, and a wide range of value-added products. It can be converted into urea, fertilizers, methanol, water gas, methane, liquid fuels, syngas, and other useful chemicals. Commonly, it is mineralized into carbonates, polycarbonates, polymers, plastics, and bags. It is used for decaffeination in addition to its usage as an extraction for flavors, and fragrances. Biological conversion of CO₂ into algae, GHG, food and fuels happens all the time.

Fig. 4 Current status of fossil fuel reserves.

Fig. 5 On site CO₂ capture and sequestration options.

Nature uses sunlight and water to convert CO₂ into sugars and oxygen to support the life cycle. In short, the CO₂ is being used to produce a wide range of biomass products from foods to fuels as shown in [Fig. 6](#).

Captured CO₂ may be used as an inert agent for injecting into metal casting, as aerosol for propelling, and as dry ice pellets for blasting. It is being used for carbonization and fire extinguishing. K₂CO₃/Al₂O₃ adsorbents remove CO₂ from the flue gas ([Sengupta et al., 2015](#)) and amino acid salts for capturing CO₂ at high temperatures ([Yang and Wu, 2013](#)). Liquid absorption costs \$54 to \$64 per ton of CO₂ separation using 200 to 230 kWh energy. Solid absorption costs \$144 to \$186 per ton of CO₂

Fig. 6 An outlook to past, present, and future utilization of CO₂. IGCC, integrated gasification combined cycle.

separation using 640 to 680 kWh energy. Membrane technique may offer lower costs, when well developed (I2CNR, 2012). Microporous carbon such as African palm, Malaysian coconut, and spine nut shells by KOH activation leads to CO₂ capture (Deng *et al.*, 2014; Ello *et al.*, 2013). CO₂ sorption in coal depends on the pressure, which is viewed as a good carbon sequestration medium (Baran *et al.*, 2014). Calcium oxide powder under biomass gasification conditions captures CO₂ to form CaCO₃ under the carbonization process converting back into CO₂ in the calcination process. Akin to Lee and Shin's CO₂ capturing model in dry and wet steam the carbonization and calcination processes continuously capture and store CO₂ from plant and air (Kenarsari and Zheng, 2015). CO₂ capture and separation using porous materials and converting it into fuels, chemicals, minerals, and value-added products are global research priorities (Saleem *et al.*, 2015).

To convert CO₂ into chemicals on an industrial scale, it may be captured at the precombustion, postcombustion, or oxy-combustion stages in coal fired power plants in addition to absorption, adsorption, and separation techniques (Spigarelli and Kawatra, 2013). CO₂ may be used for enhanced oil and gas recovery (EOR, RGR), and enhanced coal bed methane (ECBM) to increase productivity of oil and gas. Injecting CO₂ into depleting oil wells, for EOR, is providing 5% of US oil production and is perceived to have further potential of 60 billion barrels in recoverable crude resources (Charles, 2012). Power plants, industries, and transport sectors are major sources of CO₂ emissions, which can be sequestered and transported to the oil fields at remote locations. CO₂ generated during methane combustion can be converted into water and gas (syngas) at 41% efficiency (Chen, 2014). Solvent absorption method has gained acceptance yet recovery of CO₂ again requires energy. Nanostructure silica with titanium metal was successfully used to convert CO₂ into fuels (Akhter *et al.*, 2014). Three phase (gas/liquid/solid) interface is another method to convert CO₂ into ethylene and fuels (Aeshala *et al.*, 2013; Ogura, 2013).

Photocatalytic reduction of CO₂ with H₂O on highly dispersed Ti-oxides anchored on porous silica glass produces CH₄, CH₃OH, and O₂ (Anpo, 2013).

Incorporation of metal nanoparticles in mercaptosilica enhances CO₂ adsorption capacities (Khdary and Ghanem, 2014; Khdary *et al.*, 2014). TiO₂ and platinum particle photoelectrodes in H-type cell may be integrated with sunlight carrying glass fibers to separate O₂ and H₂ from H₂O. Nitrogen-modified titanium oxide (TiO₂/N-100) photocatalyst expedites CO₂ adsorption in aqueous solution to produce methanol (Michalkiewicz *et al.*, 2014).

TiO₂ photocatalysts convert CO₂ into methane (Cybula *et al.*, 2015) and Cu or Co-TiO₂/ZSM-5 photocatalysts convert CO₂ into many energy products under low irradiation. Solar thermal energy was reported for use to convert CO₂, NaCl, and H₂O into Na₂CO₃ and HCl products (Forster, 2014). Nanoparticles-based TiO₂ photocatalysts (CdS/TiO₂) convert CO₂ into CH₄ and CO, which may be mixed with hydrogen to produce water gas (Ahmad, 2014). Thermal, electrochemical, and photochemical techniques of converting CO₂ into fuels and chemical products are under intensive investigation worldwide (Grace *et al.*, 2014; Hu *et al.*, 2013). CO₂, H₂O, and H₂ provide a route to infinite syngas energy. CO₂ is abundantly available and hydrogen may be produced by electrochemical (electrolysis), photobiological, photoelectrochemical (photolysis), thermochemical (thermolysis), and thermal decomposition techniques such as pyrolysis and gasification (Chen, 2014).

A fluorine modified Cu/Zn/Al catalyst has shown superior performance of CO₂ hydrogenation to methanol (Gao *et al.*, 2013, 2014). Bimetallic Fe-Co catalysts improve CO₂ hydrogenation to higher order hydrocarbon fuels (Sathawong *et al.*, 2013, 2014b). CO₂ is being investigated to form oxazolidinone for medicinal applications (NEAF, 2010). Selection of a catalyst for methanation is a highly selective skill (Dăce *et al.*, 2014).

Protic ionic liquids are efficient catalysts to form cyclic carbonate from CO₂ and epoxides (Xiao *et al.*, 2014). Steel industry waste slag based catalysts are used for fixation of CO₂ to produce cyclic carbonates (Kuwahara and Yamashita, 2013; Sun *et al.*, 2013). CO₂ dry reforming of methane is a highly endothermic process giving of water gas (Pakhare *et al.*, 2013). Ruthenium substituted La₂Zr₂O₇ pyrochlore improves dry CO₂ reforming of methane. Carboxylation of olefins and alkynes with CO₂ gives acrylic acids and carboxylic acid salts, which is a new scenario for green and sustainable chemical industry (Hwang and Radermacher, 1999; Yu *et al.*, 2013).

CO₂ is no more a waste product as it is a raw feedstock for fuels, chemicals, polymers, and value-added industrial products. CO₂ is perceived as precious raw material for a wide range of innovative products. Smart CO₂ transformation (SCOT) is a strategic European agenda focusing on technical and economic performance of emerging CO₂ transformation technologies. CO₂'s use, recycling, and reuse make a useful raw material supporting multiple industries, for example, food processing, pulp and paper, beverages, metal, and refrigeration and chemical industries (Koljonen *et al.*, 2004). Current utilization of 600 Mt/y CO₂ in the chemical industry is a minor fraction (1.5%) of global CO₂ emissions into the atmosphere. Changing paradigm of CO₂ utilization would lead to inventory applications (Aresta *et al.*, 2013; Aresta, 2010). Hydrogenation of CO₂ to methane and methanol (Miguel *et al.*, 2015), synthetic gas (Stechel and Miller, 2013) by electrolysis (Agrafiotis *et al.*, 2015) or thermolysis (Ermanoski *et al.*, 2014) and conversion of CO₂ into a wide range of value-added products is the precursor of a future CO₂ economy (Saeidi *et al.*, 2014).

Active Communications International (ACI) has played a great role in the promotion of CO₂ utilization by mediating international conferences. ACI conducted the latest CO₂ utilization conference (focusing on widespread industrial applications of CO₂) from 25 to 26 February 2015 in San Antonio, United States. Before this, ACI conducted a CO₂ utilization conference (focusing on CO₂ as a useful raw material) from 19 to 20 February 2014 in San Diego, United States and earlier than that ACI mediated a CO₂ utilization summit (focusing on conversion of CO₂ into fuel's 7 chemicals) from 30 to 31 October 2013 in Brussels, Belgium. In addition to ACI CO₂ utilization conferences, the ASME supercritical CO₂ power cycle symposium in 2012, APTA 2013, SES 2013, Chinese low carbon earth summit in 2014, Dutch CCS GHGT-12 symposium in 2014, Norwegian TCCS-9 in 2015, and ICC DU XIII conference focusing on photoelectrochemical and catalytic conversions into products scheduled for July 5–9, 2015 are promoting CO₂ utilization awareness in society. CO₂ utilization conferences, symposiums, and summits inform society by debating on technical applications. Industry experts in ACI 4th CO₂ utilization conference described the use of CO₂ in cultivation, conversion of CO₂ into polymers, plastics, bags, and bottles, utilization of CO₂ in geothermal systems, the use of CO₂ in the oil and gas industry for enhanced fuel extraction, CO₂ mineralization, and conversion into building construction materials.

CO₂ Industry Impediments

Carbon dioxide is thinly distributed in the air. It can be better captured at source as coal fired power plants produce 42% of all fossil fuels related emissions. Currently, 96% of organic chemicals are derived from the fossil fuels. Hydrogenation of CO₂ into hydrocarbon fuels and recycling into chemicals and industrial materials would mitigate the climate change process. Development of efficient electrolysis, catalysis, and thermolysis processes is the confronting challenge.

Nature converts CO₂ and water under sunshine into glucose (C₆H₁₂O₁₁), which subsequently transforms into sugars, cellulose, lignin, etc. It takes 8–10 photons to utilize one molecule of CO₂. Gibbs free energy for converting one mole of CO₂ to glucose is 381 kcal, whereas eight photons of 600 nm light have 381 kcal energy. About 45% of the light spectrum can cause photosynthesis, so the theoretical efficiency cannot be more than 30% the same as humans and engines. Due to reflection and respiration the actual plant efficiency is 1% to 10% (strictly to 3% to 6%). Our bodies and internal combustion engines convert 30% to 40% of food and fuel energies into useful power. In case of 100 J incident light flux the plants convert maximum 10 J into chemical energy which after combustion reduces to 3.5 J. Owing to low efficiency, plants waste more than 94% of solar energy (FAO, 1997). Photocatalytic oxidation and reduction reactions lead to the production of HCOOH, CH₃OH, and CH₄. Design of photoanodes, photocathodes, and nanostructured catalysts are frontiers of the modern research and might break the rocky barrier (Ohno, 2017). Photobioreactors convert CO₂ into fatty acids, lipids, proteins and other biodegradable products. Binary cultures of phototrophs and heterotrophs in photobioreactors can provide a sustainable closed loop environment. Modular bioreactors show promise of carbon neutral economies in protein production, pharmaceuticals, biofuels, amino acids, vitamins, and animal foods (photobioreactors).

Solar hydrogen produced by photoconversion using photocatalytic, photoelectrochemical, and photobiological processes is more environment benign than syngas produced by gasification (Abbasi and Abbasi, 2011). Photoelectrodes are made of doped semiconductor materials. A broader band gap enhances the absorption spectrum and narrow band gap promotes charge transportation. Photoelectrode surface is specially treated to reduce recombination and it is morphologically controlled to enhance absorption and to shorten the transport of charges. It needs a sensitizer to improve photoelectrochemical efficiency. In the photobiological process the hydrogenases have the capability to consume and create molecular hydrogen. Biophotolysis uses organisms to transform solar energy into chemical energy. Photoelectrolysis needs efficient electrode materials that do not yet exist (Huang, 2014).

According to Club CO₂, France and Geogreen (2011), today's major CO₂ applications are EOR (pressure), heat transfer (refrigerant), flame retardation, foods, beverages, and inert agents, which are likely to expand to dry cleaning (solvent) and hydrogenation and microalgae to produce hydrocarbons (HCs) and biofuels. CO₂ medium term applications include microalgae bioreactors, ex situ mineralization, and hydraulic fracturing in shale beds. Long-term applications would be catalytic conversion, in situ mineralization with IGCC plants, electrolytic conversion by artificial photosynthesis, and high flux solar driven thermochemical dissociation (thermolysis). At the moment catalysis, electrolysis, and thermolysis technologies are not cost effective, due to their lower efficiencies, which are the primary focus of researchers worldwide.

Researchers might develop cost effective CO₂ capturing membranes, catalysts, and electrolytic electrodes in the short term but in situ mineralization and efficient photoelectrolyzers would take time. Taniguchi's membrane operates under 30 and 1.0×10^{-10} m³(STP)/(m² s Pa) conditions, which need to improve to the 7.5×10^{-10} m³(STP)/(m² s Pa) level. As the CO₂ permeance depends on membrane thickness (10–500 μm), so it is a diffusion controlled device. Membrane thinning, akin to morphology controlled nanostructured photoelectrolytic electrodes, is a material science limitation. Composite organic and inorganic materials are being investigated to design CO₂ absorbing porous structures. Large MOF structures' membranes have poor adsorption and sorption properties. Atomic and molecular engineering tools, ideally, allow the fabrication of perforated thin membranes to separate any gas from random air mixture. A thin structure, smaller than 100 nm, may exhibit nonlinear behavior. I²CNER have identified three catalyst materials for selective conversion of CO₂ into CO. Nakashima, Fujigaya, and Gewirth focus on polymer wrapped, multiwall, nanotube supported nanoparticles. Gewirth concentrates on organometallic catalysts and Lyth on metal carbonitride catalysts yet nothing is on the market with faradic efficiency > 95%, energetic efficiency > 60% with 200 mA/cm² current densities (Shigenori, I²NCR). There are many biological, photochemical and photobiological pathways to convert CO₂ into fuels and chemicals, yet efficient catalysts and photocatalysts limitations do not let the process to go ahead. Anyhow, recycling CO₂ into value-added products might be a possible worthy answer to get rid of climate change over time (Huang, 2014). Catalysts are a tough science behind energy and climate change crises.

George Washington University's solar thermal electrochemical photovoltaic (STEP) process converts solar energy at 35% under 50 sunlight flux and at 37% under 500 sun's fluorescence. STEP used 2.7 V electricity to drive two molten electrolysis cells in series at 750°C to generate CO at 1.3–1.5 A on 0.9 V. About 700 km² area can effectively remove atmospheric CO₂ from air. Cost effective conversion of CO₂ into oils and H₂ is yet a remote reality, however climate considerations might dictate its urgency. The energy, population, food, and environmental problems are interrelated, so the cost factor will have to be adjusted elsewhere. Chemical and biological conversion of CO₂ is at least a viable routine if all alternatives fail (Hall and House, 1994). The good behind the CO₂ business is cost effective capture and utilization of CO₂ to reduce GHG emissions. Underground natural CO₂ reservoir costs 5–10 \$/t, which is 5–10 times cheaper than available CO₂ capturing alternatives. Scientists are developing innovative techniques to reduce capturing costs yet the desired technology has a long way to develop before it gets competitive with naturally occurring CO₂. The hurdle in CO₂-based products is that they are still more expensive than the earth based alternatives. Even the competitive CO₂ capturing and conversion costs will hardly make a small dent in annual 40 GtCO₂ emissions. CCS akin to solar technology will take a couple of decades to be cost effective. Current cement, timber, and plastics consumption is 6.25 billion tons, which may increase to 20 billion tons per year by 2100. Carbonization of beverages uses hardly 1 MtCO₂/y, which releases into the atmosphere on opening the bottles. We might need to decarbonize the future economy, which would depend on CO₂ fuels. We would need to pursue alternative ways to sequester CO₂ emissions, for example, by storing carbon in soils, trees, fertilizers, or underground reservoirs (Daily Western, 2014).

Unfortunately, utilization of CO₂ as feedstock does not contribute to the mitigation of greenhouse effects, even though CO₂ stands as a green reactant (Sakakura *et al.*, 2007). The chemical (or biochemical) fixation of CO₂ does not imply a reduction of CO₂ emissions as its transformation requires energy both to drive reaction (high temperatures and pressures) and separate products (separation occurs at low pressures and, hence, recycling unreacted CO₂ to the reactor requires recompression at the expense of high energy input). The energy demand of the world in order of magnitude is higher than the amount of CO₂ fixed by chemical utilization of CO₂ (Westenhaus, 2010). In the critical phase of its life cycle, organic chemicals will emit CO₂. Nevertheless, the relevance of CO₂ as raw material stands for being a renewable feedstock, replacing cost effective conventional fossil based routes. Industrial synthesis of fertilizers and carbonates involves CO₂. Global use of fertilizers (with 46% nitrogen) was 198.4 Mt in 2013, which is expected to increase to 236.3 Mt by 2017. Current utilization of CO₂ is lesser than the even anthropogenic emissions of 2.5 GtCO₂ every year (Abas *et al.*, 2014).

Revival of CO₂ (R-744) as Next Generation Refrigerant

CO₂ has been used as a refrigerant before 1950 in marine applications and later replaced by synthetic refrigerants. Though the Montreal Protocol (1987) banned the production and use of CFCs after 1995, some countries are still using them. The Kyoto

Protocol (1997) endorsed to limit the use of hydrochlorofluorocarbons (HCFCs) by virtue of their higher GWP by 2015 and time barred permission to use HFCs by 2020 for developed countries and 2030 for developing countries (Yang and Wu, 2013). The deadline is quite near yet many countries are unaware or reluctant to replace the existing refrigerants. F-gas law in Europe was implemented from January 2015, as a quest for low GWP in mobile air-conditioning devices saying goodbye to high GWP refrigerants. The F-gases include HFCs, PFCs, and sulfur hexafluoride (SF₆). Existing refrigerants do not fulfill the Montreal and Kyoto protocols and F-gas laws and will be replaced. The American Society of Heating Refrigeration and Air Conditioning (ASHREA) envisaged HCs, water, ammonia, and CO₂ as future natural refrigerants. HCs are flammable, water freezes below zero, and ammonia is toxic and reactive with copper. CO₂ (R-744) exhibits low critical temperature (31.1°C) and high critical pressure (73.3 bar), which requires transcritical operation in the propriety vapor compression cycle. This lowers the performance of CO₂-based cooling (Lorentzen, 1994) systems, whilst a lot of practical implications have been suggested by various authors for efficiency enhancement in CO₂-based refrigeration and air-conditioning systems (Robinson and Groll, 1998; Kim and Kim, 2002). However, in water and space heating the transcritical cycle operation appears to be more efficient as compared to other refrigerants (Neksa *et al.*, 1998). We have taken into account the lower critical temperature and high pressure of CO₂ as an opportunity and have designed a gravity driven solar water heater, which can work efficiently in mild sunshine (subzero temperature areas) with superior (80%–85%) collector efficiency (Abas *et al.*, 2017). The proposed system works in the supercritical phase employing evacuated glass tube collector with copper based U-tube heat removal system as shown in Fig. 7.

DENSO Japan introduced the eco-cute model of CO₂ fluid mediated heat transfer, which is getting very popular. When CO₂ is used as refrigerant in supermarkets the coefficient of performance for 90% of the year is higher than HFC based systems. Production and transportation of CO₂ have carbon equivalent of 1 kg CO₂-eq per kg, whereas NH₃ and HFC have equivalent carbon equivalent of 2 and 9 kg CO₂-eq per kg.

CO₂ Conversion Challenges

Carbon dioxide conversion bottlenecks include cost effective separation membranes, efficient photoelectrolytic electrodes, and smart chemical and enabling biological catalysts (Song, 2006; Li *et al.*, 2013). Extensive literature is available on CO₂ as raw feedstock (Aresta, 2010), yet CO₂ business does not compete in the interest driven market. We have to bend our necks upward to envision the high target of 40 GtCO₂ per year. Syngas based products, prepared by Fischer–Tropsch method, look promising for

Fig. 7 CO₂ Mediated solar water heater. Reproduced from Abas, N., Khan, N., Haider, A., Saleem, M.S., 2017. A thermosyphon solar water heating system for sub zero temperature areas. Cold Regions Science and Technology 143, 81–92. Available at: [doi:10.1016/j.coldregions.2017.08.012](https://doi.org/10.1016/j.coldregions.2017.08.012).

the production of synthetic fuels like olefins, naphtha, and diesel. Methanol may be promoted as hydrogen carrier and feedstock or transesterification agent in biodiesel and dimethyl carbonate (DMC) production processes. The use of CO₂ as a carbon source in sustainable chemistry could be a profit oriented business. Conversion of CO₂ into chemicals is not considered a sustainable solution of GHG emissions as only 110 Mt of CO₂ is used in production of chemicals. Simply the conversion of CO₂ into energy products means the use of more hydrocarbon fuels. The synthetic fuels, for example, methanol (38), DMC (40), and dimethyl ether (DME) (52), have a lower percentage number of carbon atoms, so the heating values compared to propane (82), gasoline (85), and diesel (86). DMC acts as a carbonylation agent to replace hazardous phosgene in the synthesis of polycarbonate. DME is considered better than liquefied petroleum gas (LPG) and diesel for gas turbines. Pyrolysis and gasification techniques (Freitas and Guirardello, 2015) produce combustible syngas (Freitas and Guirardello, 2014) that again transforms back into CO₂, so it is not a very effective GHG mitigation process.

Climate change is recognized as a real extinction threat. Conversion of CO₂ in fuels and chemicals is perceived as it affects the environment (van der Giesen *et al.*, 2014; Cuéllar-Franca and Azapagic, 2015). There is a complete concurrence on cost effective utilization and efficient conversion of CO₂ into chemicals, minerals, fuels, and polymers to cope with climate change challenges.

CO₂ (R-744) has a vast potential in next generation refrigeration and heat pump applications. It has zero-effective GWP and ozone-depletion potential (ODP), and is nonflammable, cost effective, has a high working temperature range, and is easily available everywhere. The potential challenges, while using R-744 as a refrigerant in cooling applications includes heat rejection in transcritical cycle, high pressure compressors, throttling losses, low COP, and high system cost. Contrary to this when R-744 is employed for heating applications, which includes 47% of world's final energy utilization, it has superior performance compared to other refrigerants.

Conclusions

Population growth, rampant energy demands, and burgeoning economies are recognized to drive the climate change process. Natural greenhouse effect index due to natural water vapors and preindustrial level of CO₂ concentrations was 1.0, which has increased to more than 1.34 in recent decades. Climate change is affecting humans, animals, and trees. Stretching summers with intense heat waves and shrinking winters with extreme chills are the signs of peaking energy demands. We are entering into a vicious cycle in terra incognita. IPCC assumes, if the problem in this case, i.e., high CO₂ concentrations, is engineered to be a part of the solution by CO₂ storage, utilization, and conversion business, then the free market based corporate culture can reduce its concentrations to decelerate the climate change process. Interest driven carbon business can harness this global problem. Conversion of CO₂ into fuels and value-added products sounds good yet it needs efficient membranes, catalysts, and photoelectrodes, which are not available in the market. Short term research and energy transition processes require trillions of dollars to continue meeting energy demands by mitigating climate change.

Acknowledgments

This research was in part supported by a grant from the Pakistan–US Science and Technology Cooperation Program (Project ID No. 299), US Department of State (jointly administered by the National Academics and Higher Education Commission of Pakistan).

 T Temperature [$^{\circ}\text{C}$ or K]
 U Overall heat loss coefficient [$\text{W m}^{-2} \text{K}^{-1}$]

Introduction

Parabolic trough collectors (PTC) are the most mature solar energy concentration technology that are now available on a commercial-scale. They have also intensively researched and today numerous prototype configurations and mathematical models are available in the scientific literature. Standard module sizes for single-axis tracking collectors are usually used in electrical power generation using concentrated solar energy. The use of parabolic trough solar collectors for process heating applications (up to 250°C operating temperatures) has numerous success stories all over the world. These types of installations normally involve utilization of small-sized parabolic trough solar collector systems. In most of cases, thermal oils are used in the collector loop as heat transfer fluids while in some cases, water is used as the working medium for direct hot water production or steam generation. The application range of such systems include industrial hot water or steam generation, solar cooling, desalination and the organic Rankine cycles for power generation.

An example of a commercialized small-scale parabolic trough collector system is shown in Fig. 1 (PolyTrough, 1800). The system is suitable for low-medium temperature applications with a single-axis tracking control system. Pressurized water or thermal oil can be used as heat transfer fluids.

In addition, systems with light structures and low cost technology for process heat applications up to 400°C could be obtained with parabolic trough collectors. They can effectively produce heat at temperatures between 50 and 400°C (Kalogirou, 2004).

PTC systems usually track the sun with one degree of freedom using one of three orientations: east-west, north-south or polar, Fig. 2 (Solar Photochemistry Technology). The absorber of a PTC is usually tubular, enclosed in a glass cover envelope to reduce radiative and convective losses. The convective losses can be minimized by creating a vacuum in the annular space between the absorber and the glass cover (Goswami *et al.*, 2000).

For linear concentrators, the thermodynamic limit for the concentration ratio is around 215, as demonstrated by Rabl (1975). Medium concentration parabolic trough collectors are very attractive for solar designers and thus highly researched for medium temperature applications. In most cases, a tubular receiver is implemented with a metal pipe coated with a selective absorbing material inside an evacuated glass envelope.

System Description and Components Design

Fig. 3 shows the flow diagram of the proposed parabolic trough collector system. The system consists of a small-scale parabolic trough reflector and its supporting structure, thermal receiver, thermal energy storage, circulating pump, heat transfer fluid conductors, tracking

mechanism and a controller. The system design is simple and cost-effective in terms of material selected and thermal equipment structures. A small circulation pump conveys the heat transfer fluid (water) through the collector and thermal storage tank circuit. Concentrated solar rays on thermal receiver raise the heat transfer fluid temperature which in turn discharge thermal energy into the storage tank through the integrated helical heat exchanger. The thermal load profile during the day specifies the effective storage temperature. The main function of the controller is to ensure sun tracking of the PTC from sunrise to sunset. Other tasks include managing operation of circulation pumps or regulation of the heat transfer fluid flow rate, if applicable.

Parabolic Reflector and Thermal Receiver

Parabolic geometry

Fig. 4 shows the generic parabolic geometry, where the fixed line is called the directrix and the fixed point F is the focus. The parabola intersects its axis at a point V , called the vertex (Stine and Geyer, 2001).

If the origin is taken at the vertex V and the x -axis along the axis of the parabola, the equation of the parabola is

$$y = \frac{x^2}{4f} \quad (1)$$

where f is the focal length.

Fig. 4 Generic parabolic geometry.

If the origin is shifted to the focus F , as is often done in optical studies, the equation of a parabola becomes

$$y = \frac{x^2}{4f} - f \quad (2)$$

Once a specific portion of the parabolic curve has been selected (W), the height of the curve, h may be defined as the maximum distance from the vertex to a line drawn across the aperture of the parabola, i.e:

$$h = \frac{W^2}{16f} \quad (3)$$

Using the geometry of **Fig. 4**, the local rim angle ψ is double the reflection angle θ for a point on the parabolic curve. The rim angle ψ_{rim} may be found in terms of the parabola dimensions as

$$\tan(\psi_{rim}) = \left[\frac{W}{8h} - \frac{2h}{W} \right]^{-1} \quad (4)$$

Another property of the parabola that may be of use in understanding solar concentrator design is the arc length S ,

$$S = \left[\frac{W}{2} \sqrt{\left(\frac{4h}{W} \right)^2 + 1} \right] + 2f \ln \left[\frac{4h}{W} + \sqrt{\left(\frac{4h}{W} \right)^2 + 1} \right] \quad (5)$$

The following equivalencies are given for the convenience in evaluating parabolic geometry and related optical derivations:

$$\tan\left(\frac{\psi_{rim}}{2}\right) = \frac{W}{4f} \quad (6)$$

$$\frac{f}{W} = \frac{1 + \cos(\psi_{rim})}{4\sin(\psi_{rim})} \quad (7)$$

Fig. 5 shows the parabolic trough reflector profile and thermal receiver selected for the study.

Supporting structure

The proposed supporting structure is designed with a parabolic profile to carry the solar reflectors and to allow for solar tracking in an efficient way. The rotating reflector supports and thermal receiver assembly is shown in **Fig. 6**. The selected material for the reflector supports is wood for its less weight and sustainability. Woodchips can also be used with proper forming in a special die. The parabolic reflector material is selected to be polished metal sheets with back insulating coating.

Thermal Receiver

The thermal receiver is a steel pipe with the exposed half surface area coated with a selective coating (high temperature selective black paint) and the other half is thermally insulated. Metal tie rods connecting the reflector supporting structure are separated by 1 m for each reflector support along the trough length. Receiver supports connect the thermal receiver and reflector supports to hold the thermal receiver.

Fig. 5 Parabolic trough reflector profile and the thermal receiver.

Fig. 6 Rotating reflector supports and thermal receiver assembly.

Thermal Energy Storage Unit

A cylindrical thermally insulated tank, made from recycled plastic, with 0.3 m^3 storage capacity is attached to the collector system for daily energy storage. A helical heat exchanger is integrated inside the storage tank and is made from copper. Hot water is drawn from the tank according to thermal load profile while makeup water is continuously supplied into the tank.

Heat Transfer Fluid Circulation System

The piping connecting the parabolic trough collector receiver with the thermal energy storage unit are made from insulated polypropylene (PPR) plastic, except for terminal flexible joints that are made from thermal plastic. In addition to circulating the heat transfer fluid through the collector circuit, the circulating pump slightly pressurize the fluid in order to maintain liquid-phase flow under the operating temperature range.

Controller and Tracking Mechanism

A DC stepper motor drive is used to supply the parabolic reflector structure with the power needed for solar tracking. The parabolic trough orientation is selected to be N-S aligned with single-axis tracking. The controller design is based on calculating solar angles according to local time, date, latitude and longitude of the collector location. A 1:1 gear ratio is selected, since the light weight of the supporting structure allows for low-torque requirements. [Fig. 7](#) shows an illustration of the tracking mechanism.

Fig. 7 Tracking mechanism for the small-scale PTC.

Table 1 Design parameters and materials of the parabolic trough solar collector.

Component	Parameter	Value	Material
Parabolic concentrator	Focal length [m]	0.60	Reflector supports: wood or woodchips Reflectors: polished steel sheets
	Parabolic arc length [m]	1.25	
	Aperture width [m]	1.20	
	Parabolic curve height [m]	0.15	
	Rim angle [°]	48.06	
	Parabolic trough length [m]	2.50	
	Metal sheet reflectivity [–]	0.90	
Absorbing coating	Absorptivity [–]	0.80	High-temperature paint
	Emissivity [–]	0.10	
Thermal receiver	Outer diameter of absorber tube [m]	0.0254	Carbon steel
	Inner diameter of absorber tube [m]	0.0194	
Thermal storage	Volume [m ³]	0.30	Plastic
Heat exchanger	Coil diameter [m]	0.20	Copper

The design dimensions, materials selected and computational parameters of the parabolic trough collector are summarized in [Table 1](#).

Mathematical Model

The mathematical model of the parabolic trough collector system is essentially dynamic, i.e., parameter simulation should be done in dynamic states. For this reason, a time-step simulation environment is employed for model building and performance evaluation of the parabolic trough solar thermal collector. High resolution (minutely) solar irradiance and meteorological data are obtained from the weather and solar monitoring station available at the Solar Energy Conversion Laboratory, Cairo University, Egypt (E 31° 00′ 30″, N 30° 02′ 10″). These data are used for assessing the performance of the system under real dynamic conditions.

Four demonstrative days during the year 2017 are selected to examine the system performance under dynamic conditions: vernal and autumnal equinoxes (March 20 and September 23), summer and winter solstices (June 21 and December 22). [Fig. 8](#) shows direct normal irradiance (DNI), ambient temperature (T_a) and wind speed (V_w) for equinoxes and solstices days, input to the mathematical model. For each day, fourteen hours of exposure, from 05:00 AM to 07:00 PM local time are assigned.

Optical Analysis

The optical efficiency model of the parabolic trough collector is given by

$$\eta_{opt} = \rho \alpha \gamma K_0 \quad (8)$$

where ρ is reflectivity of the metal reflectors, α is the absorptivity of the absorbing coating and γ is the intercept factor. A 2-D ray

Fig. 8 Demonstrative days for the evaluation of performance of the PTC under dynamic conditions.

Fig. 9 A 2-D ray tracing diagram for optical performance of the PTC under dynamic conditions.

tracing analysis is performed for the ideal parabolic trough reflector profile and the results are shown in [Fig. 9](#). A practical value of $\gamma=0.95$ is used in the simulation to account for assembly and tracking errors.

The incidence angle modifier, IAM, factor (K_θ) is an extra loss due to the change of optical properties of the receiver materials with off-normal incidence angles. For single-axis parabolic trough collectors, the IAM model is given by [Eq. \(9\)](#). The constant b_o ranges from 0.27 to 0.4 for the EuroTrough prototype, as specified by the German Aerospace Center (DLR). An average value of $b_o=0.33$ is used for the present study.

$$K_\theta = 1 - b_o \left(\frac{1}{\cos(\theta)} - 1 \right) \quad (9)$$

where θ is the longitudinal component of the incidence angle of solar rays on the collector aperture.

Thermal Analysis

For the thermal receiver, it is assumed that all thermal losses are referred to the absorber area. The useful heat gain, $\dot{q}_u$ can be given, respectively, by [Eqs. \(10\)](#) and [\(11\)](#).

$$\dot{q}_u = h_{f,conv} A_{w,i} (T_{w,i} - T_f) \quad (10)$$

$$\dot{q}_u = \dot{m}_f c_{p,f} (T_{f,out} - T_{f,in}) \quad (11)$$

where $h_{f,conv}$ is the convection heat transfer coefficient of the working fluid inside the receiver, $A_{w,i}$ is the inner surface area of the absorber tube, $T_{w,i}$ is the wall inner temperature of the absorber tube and T_f is the mean fluid temperature of the heat collection element inside the absorber tube. The convection heat transfer coefficient $h_{f,conv} = Nu_f \lambda_f / D_{p,i}$, where Nusselt number (Nu_f) is given by Incropera *et al.* (2007).

$$Nu_f = \begin{cases} 1.86 \left(\frac{Re_f Pr_f}{L/D_{p,i}} \right)^{1/3} \left(\frac{\mu_f}{\mu_w} \right)^{0.14} & (Re_f \leq 2300) \\ \frac{(f/8)(Re_f - 1000)Pr_f}{1 + 12.7(f/8)^{1/2}(Pr_f^{2/3} - 1)} & (Re_f > 2300) \end{cases} \quad (12)$$

with $f = [0.790 \ln(Re_f) - 1.64]^{-2}$, $Re_f = 4\dot{m}_f / (\pi D_{p,i} \mu_f)$ is the Reynolds number of the fluid based on the inner tube diameter $D_{p,i}$ and Pr_f is the Prandtl number. $\dot{m}_f$ is the mass flow rate of the working fluid. Thermophysical properties of the heat transfer fluid are calculated based on the mean fluid temperature (T_f).

The useful heat gain is also calculated from the absorbed solar power reduced by thermal losses, Eq. (13). The absorbed solar power is given by Eq. (14) and the thermal losses is given by Eq. (15).

Fig. 10 Simplified block diagram of the simulation model.

Fig. 11 Tracking angle of the parabolic trough collector for different simulation dates.

Fig. 12 Overall efficiency of the parabolic trough collector for different simulation dates.

Fig. 13 Thermal storage temperature variations for different simulation dates.

$$\dot{q}_u = \dot{q}_p - \dot{q}_L \quad (13)$$

$$\dot{q}_p = \eta_{opt} \cdot DNI \cdot \cos(\theta) \cdot A_{ap} \quad (14)$$

$$\dot{q}_L = U_L A_p (T_p - T_a) \quad (15)$$

U_L is the overall heat loss coefficient.

Thermal Storage

The governing equation for the unstratified thermal energy storage tank, the heat exchanger and the thermal load is given by the relation (combined characteristics)

$$(mc)_s \frac{dT_s}{dt} = \dot{q}_u - \dot{q}_{Load} - \dot{q}_{L,s} \quad (16)$$

where $(mc)_s$ is the heat capacity of the thermal storage tank, $\dot{q}_{Load}$ is the thermal load profile and $\dot{q}_{L,s}$ is the thermal losses from the storage.

Results and Discussion

In order to produce simulation outputs for the single-axis parabolic trough solar collector, the developed mathematical model is implemented within a dynamic simulation environment under the pre-specified operating conditions. Numerical simulation algorithms are implemented in MATLAB-Simulink (MATLAB-Simulink Release, 2015b) environment to solve the developed sets of nonlinear algebraic and ordinary differential equations forming collector system models. Simulation outputs for different operating conditions are presented. A simplified block diagram of the simulation model is shown in Fig. 10.

Fig. 11 shows the tracking angle of the parabolic trough collector for different simulation dates. Fig. 12 shows the overall efficiency of the parabolic trough collector for different simulation dates. Transient cloud-cover effects of solar irradiance for the selected simulation dates are reflected on some efficiency values, especially for the winter solstice. Based on an initial storage temperature of 40°C and a zero thermal load profile (charging), the variation of the thermal storage temperature with time is given by Fig. 13 for different simulation dates.

Conclusions

The article introduced a simplified design of a small-scale parabolic trough solar thermal collector with most of components made from sustainable materials. A nonlinear dynamic model of the small-scale parabolic trough collector system was built and simulated for different representative dates (equinoxes and solstices) during the year. Optical and thermal mathematical models of the collector were introduced and the overall performance was investigated. It was shown that the design of this size of parabolic trough collectors is able to provide hot water at a suitable temperature range for domestic uses. The system simplicity and effectiveness are also comparable to similar system designs utilized for domestic hot water productions under the same operating conditions.

Development of Epoxy Based Composites Using Bamboo and Waste Metal Chips

Arun C Borsaikia, Anup Kumar, Amit Raj, and Uday S Dixit, Indian Institute of Technology Guwahati, Guwahati, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Waste management is an integral part of a sustainable manufacturing system. Recently, there has been an increasing trend to use waste material as an ingredient of a composite material. For example, Thomas *et al.* (2016) replaced natural fine aggregate in a concrete by crumb waste tire rubber. Rubberized concrete can be used in an aggressive acidic environment. It can also be used in structures where there are chances of brittle failure. In a study, Thomas and Gupta (2016) observed that the crumb rubber might be used in a high strength concrete as a partial substitute for fine aggregate up to 12.5% by weight for attaining the compressive strength above 60 MPa. Similarly, granite dust has been used as a replacement of natural fine aggregate (Singh *et al.*, 2016). Other materials that have been used as the replacement of conventional aggregates are dimensional stone waste, fly ash, silica fume, slag, rice husk, ash and metakaolin (Rana *et al.*, 2016).

An important area of manufacturing requiring immediate attention for waste management is machining. Machining is one of the most widely used manufacturing processes. The chip disposal is a very important aspect of environmentally friendly machining (Dixit *et al.*, 2012). Recycling of chips, although a routine procedure in industry, needs a relook by the researchers. Some researchers have already paid attention to this activity. Gronostajski *et al.* (1996) used hot extrusion process to increase physical and mechanical properties of the chips and its alloy composites with addition of small amount of tungsten powder. Sherafat *et al.* (2009) used a small quantity of pure aluminum powder for preparing a composite material of aluminum alloy chips using hot extrusion. Mindivan *et al.* (2014) fabricated a composite using magnesium/aluminum chips and carbon nanotubes and evaluated the properties. Small addition of carbon nanotubes increased the hardness and corrosion resistance of composites compared to base alloy. Simon *et al.* (2016) reviewed the methods for recycling of contaminated metallic chips.

Karadag *et al.* (2016) prepared the composites using brass (CuZn30) and steel (S355JR) chips as constituents by cold pressing followed by liquid phase sinterization. The mechanical properties of the composite were obtained and were comparable with the mechanical properties of the bulk brass. Gronostajski and Matuszak (1999) developed the method of production of composite material by the conversion of chips directly (without melting processes) into the finished product using powder metallurgy technique followed by extrusion. The produced composites were characterised by good properties. The present work focuses on developing a composite by using metal chips. Lela *et al.* (2016) developed the mathematical model of products made from direct recycling of ENAW 2011 aluminum alloy chips by utilizing forward hot extrusion process. The influence of chip size, compaction force and extrusion temperature on mechanical properties were studied. The extrusion temperature was found to be the most significant factor influencing the mechanical properties.

Sakaray *et al.* (2012) conducted various test on Moso bamboo (a variety in China) to find their physical and mechanical properties. The tensile strength was found half as compared to mild steel. Agarwal *et al.* (2014) performed the axial and transverse loading test on bamboo reinforced columns and observed the load carrying capacity, lateral deflection, and failure mode pattern. Two-point load test was performed on beams to study their behaviour in bending. The tensile strength of bamboo-fiber reinforced plastic composite was comparatively equal to that of mild steel, whereas its density was only 12% of that of mild steel (Jindal, 1986). Zakikhani *et al.* (2014) described the processes for extracting fibers from raw bamboo culm followed by bamboo plastic composite preparation and its thermal analysis.

Chen *et al.* (1998) prepared the bamboo-fiber reinforced polypropylene composite by using maleic anhydride-grafted polypropylene (MAPP) as a compatibilizer for the composites and studied its effect on the mechanical properties of composites. Most of the properties of polyvinyl chloride (PVC)-based composites with Malaysian bamboo were compatible with wood-PVC composites, which is an evidence of potential utilization of bamboo as an alternative material for wood-plastic composites (WPCs) industry (Bahari and Krause, 2016). The utilization of Malaysian bamboo not only provides an alternative for WPCs, but also it encourages the development of thermoplastic composites towards green-oriented, cleaner production and to initiate bamboo for commercial industries in Malaysia. In this work, it was aimed to use waste metal chips for developing a sandwich-structured composite. It was attempted to develop a low cost composite using sized waste metal chips and locally available bamboo in the North Eastern part of the India. Epoxy was considered as base material for the first phase of proposed composite with waste metal chips.

Experimental Determination of Physical and Mechanical Properties of Bamboo

The properties of bamboo are affected by age, length, diameter and moisture content. Dry bamboo is used to manufacture bamboo-based product as in case of dry bamboo, properties do not change with time. Locally available matured Jati (a variety of

bamboo in India) bamboo pieces were collected for use in proposed experimental works. Procedures mentioned in relevant IS codes were adopted for determining the physical and required mechanical properties of bamboo.

Moisture Content of Bamboo

Moisture content is the quantity of water contained in a piece of bamboo and is considered to be one of the important physical parameters that reduces the strength of bamboo. In general practice, the moisture in raw bamboo is removed for further structural use of bamboo. Hence, the bamboos are seasoned naturally or mechanically. The specimens for determining moisture content were taken from the test specimens used for determining mechanical properties. In this case, three specimens with 25 mm length, 25 mm width and full wall thickness were taken for the determination of moisture content. Procedures mentioned in IS 6874: [2008] were followed to prepare specimens and to carry out test for determining moisture content. Specimen sizes were taken as per the Indian standard code. The samples were weighed correct to 0.01 g and then dried in an oven at a temperature of $103 \pm 2^\circ\text{C}$ for 24 h. The weights of specimen were observed at every 2 h interval up to total of 24 h. The final mass was taken as oven-dry mass. The loss in mass expressed as a percentage of oven-dry mass was taken as the moisture content of the test specimen. This was calculated correct to two place of decimal by the following formula:

$$\text{Percentage Moisture content} = \frac{m_i - m_o}{m_i} \times 100 \quad (1)$$

where m_i is the initial mass of the test specimen and m_o is the oven-dry mass. Normally green bamboo has an average of 50%–75% moisture content depending upon the age, season, geographical location, species and watering methods. The weights of specimen at 8, 16 and 24 h duration along with moisture content are presented in [Table 1](#).

From the observed experimental results, it is inferred that the moisture content in raw bamboo is very high. Generally, it is undesirable to use material that changes its moisture content rapidly because moisture affects the physical and mechanical properties. To overcome the problem, the bamboo pieces were kept in hot-dry oven for an average period of 8 h, because most of the moisture content is absorbed by hot-dry oven in first 8 h.

Density of Bamboo

The test specimens for determining density of bamboo were taken from the freshly felled culms with 25 mm width and 25 mm length with full wall thickness. Specimen sizes were taken as per the [Indian Standards IS 6874:\(2008\)](#). The volume of the specimens was measured by water displacement method. Two samples were taken from middle section (MS) and bottom section (BS). Specimen was weighted to an accuracy of 0.01 g. After determining green volume the specimen was immediately kept in hot dry oven. Specimen was weighted and dried thereafter. The weighing was carried out and recorded every 2 h for 24 h until the difference between successive weighing does not exceed 0.01 g, when the specimen was considered to be completely dry. The final mass was taken as oven-dry mass of specimen. The weights of specimen at 8, 16 and 24 h duration are presented in [Table 2](#).

The green volumes of bottom section and middle section were found to be 5.15 cm^3 and 5.12 cm^3 respectively. Similarly, densities of bottom section and middle section were found to be 644.95 kg m^{-3} and 625.97 kg m^{-3} respectively for oven-dry mass of 24 h. It is generally accepted that an increase in density of the culm is mainly due to thickening of the cell wall. The measurement of density at different culms gives different results.

Table 1 Moisture content in bamboo

	<i>Specimen-1</i>	<i>Specimen-2</i>	<i>Specimen-3</i>
Initial weight (g)	4.62	4.81	4.75
Weight at 8 h (g)	3.04	3.17	3.13
Weight at 16 h (g)	3.01	3.13	3.09
Weight at 24 h (g)	3.01	3.12	3.09
Total moisture content, %	34.85	34.96	35.00

Table 2 Weight of bamboo with time during oven-drying

<i>Time (hour)</i>	<i>Weight of specimen BS (g)</i>	<i>Weight of specimen MS (g)</i>
0	5.19	5.04
8	3.43	3.31
16	3.33	3.21
24	3.32	3.21

Tensile Strength of Bamboo

It is mandatory to know mechanical behaviour of raw materials prior to its use in new product. The major parameters that describe the stress-strain curve are the tensile strength, elastic modulus, percent elongation and the reduction in area, which were obtained through tensile test. In case of bamboo, specimens were prepared from the lower portion, middle portion and top portion of the dry log. Node was kept at the centre of specimen. The general direction of fibers in specimen was parallel to the longitudinal axis of specimen. In order to prepare specimen, first a bamboo was cut into two-piece length wise and the two halves were again divided longitudinally into three pieces without damaging the fibers. Fibers along the culm were distributed length wise. Universal Testing Machine (Make: Fine Testing Machine, India; Model: TUC 1000) was used to determine the tensile behaviour of reinforcing bars. Larger culms were split into approximately 19 mm wide as per the US naval laboratory recommendation or 20 mm wide as per IS 6874: [2008]. The total length of the specimens was approximately 450 mm long with a gauge length of 150 mm. Since grip length plays important role in holding the specimen without slip during test, extra length of approximately 150 mm on both ends of the specimens were kept.

The specimens were tested as per stipulations and guidelines provided in IS:6874: [2008] using Universal Testing Machine (UTM). Rate of loading was maintained at a strain rate of $6.67 \times 10^{-5} \text{ s}^{-1}$. Initially, the bamboo strip was elastically deformed giving a linear relationship of load and extension. The purpose of tensile test was to determine the tensile strength of bamboo and failure pattern with its locations, which indicates the quality of the specimen. Nine specimens were tested and the results are given in Table 3. Three samples were taken from each section of bamboo i.e., middle section (MS), bottom section (BS), and top section (TS).

It was very difficult to avoid crushing of specimen outside the gauge portion during tensile tests of specimen. This is because specimens were very sensitive to fail near the grip. In addition there was a problem of sliding of the sample in the grip before the failure in the gauge portion due to slippery nature of the material. Three types of failure patterns like typical splitting failure, typical failure at grip and typical failure at node were observed during the tests. Further, in some specimens, failure occurred firstly in the outer fibers and moved towards the core. The crack was initiated from node in the specimen and propagated towards grip because the fibers in the nodes were brittle and stiff. The fibers were much denser and disordered at nodes than those of internodes regions where fibers were straight.

From Fig. 1, it is observed that bamboo had very high tensile strength. The lower or bottom section (BS) of bamboo had less tensile strength than middle (MS) and top section (TS). This may be due to moisture retained in specimen because of thicker wall of bamboo. The middle and top section had almost same tensile strength. High tensile strength of bamboo gives high strength to composite materials.

Compressive Strength of Bamboo

The compressive strength is the property that helps a material to withstand loads acting along the axial direction. Specimen for compressive strength were taken from the lower portion, middle portion and top portion of the dry bamboo between two nodes and the length of specimens was taken equal to the outer diameter of the bamboo that was measured as described in IS 6874: [2008]. The end planes of the specimen need to be perfectly oriented at right angle to the length of the specimen. The end planes of the specimens were made flat with the help of a lathe machine, within a maximum flatness of 0.2 mm. The same UTM that was used for tensile test was also used for evaluating the compressive strength of bamboo. The specimen was placed at the centre of the platens fixed in the UTM cross head and a small load of 1 kN was applied to hold the specimen in the position. The load was applied continuously at a strain rate of $1.9 \times 10^{-3} \text{ s}^{-1}$.

The maximum compressive strength was calculated by the formula

$$\sigma_{ult} = \frac{F_{ult}}{A} \quad (2)$$

where F_{ult} is the maximum load and A is the area of cross-section of test specimen given by

$$A = \frac{\pi}{4} \{D^2 - (D - 2t)^2\} \quad (3)$$

where D is the outer diameter and t is the wall thickness. The maximum load at which specimen failed was recorded and rounded to the nearest 0.5 N mm^{-2} . Three samples were taken from each section of the bamboo i.e., middle section (MS), bottom section (BS) and top section (TS). The compressive strength of specimens is presented in Table 4. All sections of dry bamboo bear almost equal compressive strength. High compressive strength of bamboo will lead to good mechanical properties in the proposed composite material. Fig. 2 shows the stress-strain curves under compression for three sections of the bamboo. For each section, three replicates have been presented.

Table 3 Tensile strength of different section of bamboo (average of 3 replicates)

Specimen	Thickness (mm)	Width (mm)	Load (kN)		Tensile strength (MPa)	
			Average	Range	Average	Range
Bottom section (BS)	7.8	20	39.03	2.10	250.21	13.46
Middle section (MS)	5.63	20	30.10	4.00	270.26	26.61
Top section (TS)	4.6	20	22.80	2.80	248.54	30.43

Fabrication and Properties of Matrix of Waste Metal Chip

Metal chips are waste material of different machining operation like turning, milling, drilling and shaping. Metals chips are categorized based on their shapes and sizes such as continuous, built-up edge, serrated and discontinuous chips. In this work, thin threads of partially continuous waste metal chips were collected from mechanical workshop. The chip-sizes vary from 1 mm to 5 mm in length and 0.5–2 mm in width. The mix of epoxy and metal chips were used as matrix and bamboo strip as reinforcement. Araldite and Fevicol were used as epoxy whereas metal chips were used as reinforcing constituents to form a matrix. Matrix of waste metal chips and two different epoxies were prepared in different proportions of waste metal chips and individual epoxy.

The proportions of waste metal chips and Araldite (by weight) were 10:1, 10:1.5, 10:2, 10:3, 10:4, 10:5, 10:6 corresponding to SA1, SA2, SA3, SA4, SA5, SA6, SA7, respectively. Similarly, the proportions of waste metal chips and Fevicol (by weight) were 10:2, 10:3, 10:4 corresponding to SF1, SF2, SF3, respectively. The matrix prepared with Araldite worked for all the proposed mix proportions of metal chips and Araldite. Hence, seven specimen of composite have been prepared with all the seven different proportion of metal chips-Araldite mix and bamboo strips. However, in case of matrix prepared with Fevicol, only three

Fig. 2 Stress-strain diagram of bamboo under compression for (a) bottom section, (b) middle section and (c) top section.

proportions of metal chips and Fevicol worked good among more different proposed proportions. Hence, only three specimens of composites had been prepared with three different proportion of metal chips-Fevicol mix and bamboo strip. Only 10:3, 10:4 and 10:5 proportion of metal chips and Fevicol were found to be workable and result could be achieved.

Matrix of Metal Chips and Araldite

In these specimens, Araldite was used with chips for composing matrix. Different specimens were prepared with different chips to Araldite ratio. 21 specimens were prepared with seven different ratios. Specimens with less ratio of Araldite had rough surface finish than specimens with higher ratio of Araldite. The compressive strength of different specimens is presented in Table 5. The samples after testing under compression are shown in Fig. 3.

From Fig. 4, it is observed that the strength of matrix depends on proportion of chips as well as epoxy. The compressive strength of matrix first increases and then decreases with increase in the quantity of Araldite. The matrix with chip to Araldite ratio 10:4 showed higher compressive strength and thus, was used for making the new composites.

Matrix Made of Chips and Fevicol

In this case, matrix was formed by mixing Fevicol with metal chips. Six specimens were prepared from three different ratios. The compressive strength of different specimens is presented in Table 6.

From Fig. 5 and Table 6, it is observed that the load carrying capacity of the matrix was very low and the strength of the matrix depended on the ratio of chips and epoxy. The compressive strength of matrix increased first and then decreased with increase in

Table 5 Compressive strength of matrix made with metal chips and Araldite (average of 3 replicates)

Sample	Weight (g)		Compressive strength (MPa)	
	Average	Range	Average	Range
SA1	227.20	2.40	3.30	0.12
SA2	248.00	2.00	7.30	0.72
SA3	260.00	1.20	11.30	0.40
SA4	301.30	2.60	29.10	2.52
SA5	324.90	2.50	57.40	0.40
SA6	322.90	0.50	41.60	1.52
SA7	299.40	1.60	33.90	0.52

**Fig. 3** Tested specimens of matrix with metal chips and Araldite under compression (a) SA3 and (b) SA4.

the amount of epoxy. The maximum strength was observed at the ratio of 10:3 and thus, this proportion was used to form the new composites with Fevicol.

Fabrication and Determination of Properties of Bamboo-Chip-Matrix Composite

Bamboo logs of 250 mm long and strips of width 25 mm were prepared from matured bamboo. The thickness of single bamboo strips varied from 1.7 to 2.2 mm depending on position of log and type of bamboo. Three strips were joined with the help of epoxy (Araldite) side by side. The strips were joined side by side to form a flat panel of size 250 mm length and 75 mm width. In the first case, preparation of laminated composite of two layers and three layers of bamboo panels was attempted using Araldite in between to bond the bamboo panels. In the second case, specimens with bamboo-matrix composite was prepared. The matrix formed with epoxy and metal chips was again used with bamboo strip panels to give panel form of bamboo and metal chips composite. Matrix of 10:4 of metal chips to Araldite was selected to form new composite with Araldite. Similarly, matrix of chips to Fevicol ratio of 10:3 was utilized to form the composites. Specimen with thickness 14.5 mm had two layers of composite between three layers of bamboo strips and rest had one layer of composite between two layers of bamboo strips.

Fig. 4 Stress-strain diagram of matrix of metal chips and Araldite under compression for (a) SA3 and (b) SA4.

Table 6 Compressive strength for matrix made with chips and Fevicol (average of 2 replicates)

Sample	Weight (g)		Load (kN)		Compressive strength (MPa)	
	Average	Range	Average	Range	Average	Range
SF1	249.05	0.90	11.25	0.50	4.50	0.20
SF2	280.90	1.40	13.10	0.20	5.24	0.08
SF3	287.35	0.70	2.55	0.10	1.02	0.04

The prepared matrix was placed upon the prepared flat panel of bamboo strip with help of mason's trowel. The second panel of bamboo was kept upon the matrix on first bamboo panel. Both the composites were then kept on flat surface and a flat block of 10 kg weight was kept upon it to provide constant load to every part of the composite for attaining strong bonding between matrix and bamboo panel. Thereafter, the panel of both composites was cut into the specific size of 240 mm length and 20 mm width using manual hacksaw. Some of prepared composite specimens are shown in Fig. 6.

The use of epoxy (Araldite and Fevicol) between the layers of bamboo and matrix helps in protecting bamboo strips getting moisture because the epoxy is hydrophilic in nature. The preparation of matrix of metal chips and epoxy was carried out at room temperature.

Tensile Behaviour of Composite

Tensile test was performed on composites that were made up of bamboo strips, waste metal chips and epoxy. Tensile test was conducted on Universal Testing Machine model TUN 200. The middle section of 80 mm length of the specimen was considered as

Fig. 5 Stress-strain diagram of matrix of metal chips and Fevicol under compression for (a) SF1, (b) SF2 and (c) SF3.

Fig. 6 Prepared composite specimens for tension test.

gauge length and rest are kept for clamping at both the ends. The load was applied continuously at a strain rate of $1.25 \times 10^{-3} \text{ s}^{-1}$. When the composite specimen was subjected to an external tensile loading, the composite strip had undergone elastic and plastic deformation.

Tensile behaviour of composite made with only bamboo strips and Araldite

Prepared specimens with length of 250 mm were tested using relevant clauses and stipulations mentioned in IS 6874: [2008]. Three specimens for two layers bamboo strips (BL2) and three layers bamboo strips (BL3) were tested. The tensile strengths of bamboo strips are presented in Table 7. From Table 7, it is observed that the tensile strength of two-layer bamboo strip was greater than tensile strength of three-layer of bamboo strip. Fig. 7 shows the corresponding stress-strain curves.

Tensile behaviour of composite made of bamboo and matrix of metal chips and epoxy (Araldite and Fevicol)

All the specimens were prepared with matrix of metal chips to Araldite ratio 10:4. The specimens had single and two layers of matrix between two and three bamboo strips, respectively. Specimen with thickness 14.5 mm had two layers of matrix between three bamboo strips and remaining specimens had one layer of matrix between two bamboo strips. The tensile strength for different thicknesses of composite is presented in Table 8.

Table 7 Tensile strength of composite with only bamboo strip (average of 3 replicates)

Specimen	Width (mm)	Weight (g)		Tensile strength (MPa)	
		Average	Range	Average	Range
BL2	20	13.47	0.70	92.57	5.50
BL3	20	21.70	1.90	74.95	4.85

Table 8 Tensile strength for composite made with Araldite (average of 3 replicates)

Specimen	Thickness (mm)	Weight (g)		Load (kN)		Tensile strength (MPa)	
		Average	Range	Average	Range	Average	Range
TA1	15.20	156.20	3.80	11.97	4.08	39.43	13.50
TA2	12.10	111.83	10.46	12.88	5.76	54.86	20.80
TA3	8.50	66.03	3.00	10.31	1.85	59.86	10.80
TA4	14.50	123.50	7.00	9.88	0.58	34.30	2.60

**Fig. 8** Stress-strain diagram for tensile test of composites made with Araldite for (a) TA1 composites, (b) TA2 composites, (c) TA3 composites and (d) TA4 composites.

From **Table 8** and **Fig. 8**, it is inferred that different group of samples bear different level of tensile strength and strain. Further, two types of composites prepared using metal chips to Fevicol ratio of 10:3 were tested. One type had one layer of composite and two bamboo strips and other had two layers of composite and three bamboo strips forming a thickness of 14.40 mm. The tensile strength of composite is presented in **Table 9**. **Fig. 9** shows that the load carrying capacity of composites prepared with bamboo strips and matrix of metal chips and Fevicol was high and decreased with increase in thickness.

Flexural Behaviour of Composites

Flexural test is useful to determine strength of a particular element against bending due to application of load in the direction perpendicular to the axis of the element. The flexural behaviours of a beam element can be evaluated by testing the specimen with

Table 9 Tensile strength of composite made with Fevicol (average of 2 replicates)

Specimen	Thickness (mm)	Weight (g)		Load (kN)		Tensile strength (MPa)	
		Average	Range	Average	Range	Average	Range
TF1	8.60	54.15	3.70	10.85	1.35	63.15	7.70
TF2	14.40	98.20	1.60	10.18	1.47	32.56	5.07
TF3	10.60	80.45	3.10	6.73	2.33	38.60	3.20

**Fig. 9** Stress-strain diagram for tensile test of composites made with Fevicol for (a) TF1 composites, (b) TF2 composites and (c) TF3 composites.

the help of three point and centre-point loading methods. In this case second method was adopted for finding out flexural strength of composites and load was applied at the centre with the help of loading pin on the specimen supported with two pins on the opposite face of the specimen. Flexure test produces tensile stress in the convex side of the specimen and compression stress in the concave side. Centre-point bending test was conducted using Universal Testing Machine (Model: TUN 200). The load was applied continuously at constant speed of 0.1 mm s^{-1} . Following relationships were used for finding the flexural stress and flexural strain for rectangular specimen:

for flexural stress:

$$\sigma_f = \frac{3PL}{2bd^2} \quad (4)$$

for flexural strain:

$$\varepsilon_f = \frac{4Dd}{L^2} \quad (5)$$

where P is the maximum load at a given point on the load deflection curve, L is the support span, b is the width of specimen, d is the depth of specimen and D is the maximum deflection at the centre of specimen.

Flexural behaviour of composite made with only bamboo strips and Araldite

Two different types of specimens with thicknesses 4.5 mm and 7.0 mm were made ready for testing. Three samples were taken for each two layers bamboo strip (BL2) and three layers bamboo strip (BL3). The flexural strength of different layers of bamboo strip is presented in Table 10. From Fig. 10, it is observed that the load carrying capacity of three layers bamboo strip was more than that of two layers bamboo strip. The load carrying capacity for both specimens was very low.

Table 10 Flexural strength of composite made with only bamboo strip (average of 3 replicates)

Specimen	Thickness (mm)	Width (mm)	Weight (g)		Flexural strength (MPa)	
			Average	Range	Average	Range
BL2	4.50	25	18.50	1.90	46.44	2.95
BL3	7.00	25	27.50	1.40	38.78	6.12

Fig. 10 Stress-strain diagram of composites made of only bamboo strips and Araldite under bending for (a) BL2 bamboo composites and (b) BL3 bamboo composites.

Flexural behaviour of composite made with bamboo and matrix of metal chips and epoxy (Araldite and Fevicol)

In these specimens Araldite was used with chips for making composite. Different specimens were made with different amount of chips but the ratio of chips to Araldite is equal for all specimens. These specimens were made from chips to Araldite ratio of 10:4. The flexural strength of composite is presented in Table 11.

The tensile stress acted on convex side of specimen that detached bamboo strip from composite. From Fig. 11, it is observed that the load carrying capacity of specimens decreased with decrease in thickness. Generally specimen cracked at the middle where the load was applied, but in a few cases it cracked at other places due to voids created during manufacturing. The flexural strengths of specimen prepared using matrix of metal chips and Fevicol ratio 10:3 are presented in Table 12. The specimens had thickness of 14.4 mm with two layers of composite and three bamboo strips; remaining specimens had single layer of composite and two layers of bamboo strips.

Table 11 Flexural strengths of composites made using Araldite (average of 3 replicates)

Specimen	Thickness (mm)	Weight (g)		Load (kN)		Flexural strength (MPa)	
		Average	Range	Average	Range	Average	Range
BA1	15.20	184.30	4.00	1.11	0.67	57.65	34.80
BA2	12.10	134.13	3.30	0.69	0.08	57.04	6.56
BA3	8.50	84.40	2.80	0.30	0.15	52.04	19.92
BA4	14.50	152.10	0.80	0.68	0.01	39.10	0.57

Fig. 11 Load-displacement diagram of specimens under transverse loading for (a) BA1 composites, (b) BA2 composites, (c) BA3 composites and (d) BA4 composites.

Table 12 Flexural strengths of composites made using Fevicol (average of 2 replicates)

Specimen	Thickness (mm)	Weight (g)		Load (kN)		Flexural strength (MPa)	
		Average	Range	Average	Range	Average	Range
BF1	8.60	68.75	0.50	0.19	0.03	31.24	5.33
BF2	14.40	126.65	4.90	0.29	0.14	16.79	8.08
BF3	10.60	104.75	3.50	0.30	0.15	32.57	16.02

**Fig. 12** Load-displacement diagram for specimens under bending load for (a) BF1 composites, (b) BF2 composites and (c) BF3 composites.

From Fig. 12, it is observed that the load carrying capacity of specimen was very less and its deformation was very high. This is due to low compressive strength of matrix with metal chips and Fevicol which is placed between layers of bamboo strips. Its load carrying capacity was slightly higher than the load carrying capacity of bamboo strips.

Conclusions

New composites using bamboo and epoxy based matrix of waste metal chips were developed. Experimental studies were carried out on individual constituents as well as on the composite for evaluating various properties. The optimum compositions were obtained based on the experiments. The physical and mechanical properties of bamboo were affected by variables such as moisture content and presence of nodes. The strength of the matrix depends on proportions of chips to epoxy. Two epoxies were

taken: Araldite and Fevicol. Between these two, Araldite provided more flexural strength; but its cost is higher. However, the addition of chips did not improve tensile strength.

The following are the additional conclusions:

- All parts of matured Jati bamboo exhibited comparable strength properties and can be used for making composites.
- The strength of the composite depended on proportions of chips to epoxy.
- The flexural strength of composite was higher than that of bamboo strip.

Introduction

Additive manufacturing (AM) is an imaginative innovation, which defeats the inadequacies of customary strategies for prototyping. It is also known as 3D printing, added substance manufacture, or free-form fabrication. AM empowers the acknowledgment of the primary starter model of something, particularly machines or some component of the item, from which different structures or forms are produced or replicated (Gibson *et al.*, 2015; Wohlers, 2014; Doe, 2015). The selection of AM technology in development and conquering new or improving existing products is predominantly influenced by three key factors: Quality, costs and time (Gress and Kalafsky, 2015; Talić, Čikmiš *et al.*, 2014; Singh and Ranjan, 2017). Recently, AM has become a focal point of consideration for its capacity to create distinctive items utilizing different materials. Maybe printing innovations are the most well-known kind of AM that is making progress in an extensive variety of modern and academic use. The 2D and 3D printing of various materials, for example, plastics, metals, ceramics and electronic practical materials is considered as the revolutionary innovation in science and innovation. Vitrally, these advancements are being utilized widely in restorative applications. Among every single developing innovation, AM may be has the most elevated potential to fundamentally disturb the worldwide purchaser showcase as well as more specific industry parts, for example, biomedical instruments, scaffolds and inserts (Lyons, 2014; Boisvert and Adelstein, 2015). The usage of AM in the medical services industry has just brought about the advancement of devices, prosthetics, therapeutic equipment's, and inserts. All the more as of late, AM advances are being converted into the TE and regenerative medicine (RM) industry to help in the recovery of tissues and organs (Melchels *et al.*, 2012).

These days, AM has penetrated into all segment of ventures e.g., aerospace, vehicle, combat hardware, dental, electronic, design, furniture, therapeutic gadgets, and inserts (Chhaya *et al.*, 2015). No big surprise, that the TE/RM segments are likewise investigating the appropriation of different AM innovations, altering and refining the current AM advancements to fit their applications and necessities (Tumbleston *et al.*, 2015). An examination of a few driving audits and in addition industry reports proposes that the TE/RM segments could be two of the best recipients of the use of AM innovation, with clear patient, biotechnology, and therapeutic equipment's industry benefits (Huang and Leu, 2014). TE, which means to create human tissues and organs, is profiting from the reproducible, computer controlled, and exact step that can be acquired by printers. 3D printings of platforms, cell-loaded bio-materials, and cell (scaffold-free) materials hold an awesome guarantee to propel the TE field toward the manufacture of useful tissues and organs.

TE is an inter-disciplinary field in which artificial organs are built utilizing materials, cells, and development factors. Bone is a vital organ that redesigns consistently amid a person's lifetime and structures the human skeletal scaffolds. Bone TE is an imperative part of regenerative drug and biotechnology. It gives elective remedial strategies to re-establish the capacity and repair dam-matured or deteriorating bone tissue (Singh *et al.*, 2017). Biomaterials with utilitarian sub-units give focal points that advance bone tissue recovery and encourage the repair of harmed bone tissue. They have critical applications in clinical orthopaedics amid reconstructive surgeries. Auto-logous trans-plantation is the best clinical procedure since it viably joins the host bone tissue without immunogenic complexities or the infection dangers related with allogeneic sources. Auto-logous trans-plantation is viable; however the supply is restricted in view of the therapeutic and financial limitations of the world's maturing populace. Moreover, orthopaedic recreation from injury, tumours, innate deformations, and wounds are at record numbers setting expanded request on bone recovery and embed advances (Wu *et al.*, 2014). Tissue engineers create useful materials for orthopaedic remaking that can convey bio-chemical signs to cells. Under-standing the natural impacts of these materials is an essential prerequisite of TE by confirming their appropriateness and explaining the part they play in tissue development (Bauer and Muschler, 2000; Stevens, 2008). In-bone TE, substitutes are designed as platforms that are non-dangerous, bio-compatible, bio-degradable in a controlled way, and osteo-conductive (Zhang *et al.*, 2015). Fig. 1 shows step by step procedure for developing of functional tissues from biomaterials (Polymers (PEEK, PLA), Ceramics (HAP, CS) and Composites).

Calcium HAp is a manufactured material indistinguishable to the substance in teeth and bones. Calcium HAp is a critical inorganic material in biological and chemistry science. Biological apatites, which are the inorganic constituents of bone, tooth finish, and dentin, are ordinarily extremely factor in their structure and morphology, and generally contain totally different impurities. By and large, these tainted natural apatites are assigned as calcium inadequate or non-stoichiometric apatites. A noteworthy segment and a basic element of typical bone and teeth. HAp makes up bone mineral and the grid of teeth. It is HAp that gives bones and teeth their unbending nature. The 'n-HAp' is a characteristic mineral type of calcium apatite that synthetically looks like the perplexing framework of bone. Its reconstruction needs substantial mechanical strength thanks to the character of natural bone. The n-HAp is a constituent of bone (around 70%) and is utilized to expand the auxiliary unbending nature of platforms, guaranteeing their appropriateness for bone tissue development methodology. There is broad research on the

Fig. 1 Step wise process chart for creating functional tissues from biomaterials.

arrangement of bone substitutes utilizing n-HAp for biomedical applications due to the similitude of n-HAp to normal bone (Zhou and Lee, 2011). n-HAp is exceedingly osteo-conductive. It displays bone bonding limit, offers a suitable layout structure for bone arrangement, and advances cell working permitting the outflow of bone framing osteo-genic markers (LeGeros, 2002; Venkatesan *et al.*, 2015). In spite of these properties, n-HAp is weak and has constrained application in stacking bearing applications. n-HAp is frequently functionalized with different polymers, for example, CS, to give the mechanical properties required to an embed in the reconstruction and regeneration of bone, tissue (Wei and Ma, 2004; Mangano *et al.*, 2006; Piccirillo *et al.*, 2013)

Materials and Methods

Materials

Hydroxyapatite (HAp)

HAp is artificially like the mineral segment of bones and hard tissues in well evolved creatures. It is one of the suitable materials that are classed as bio-compatible and bio-active, implying that it will bolster bone ingrowth and Osseo-mix when utilized as a part of orthopaedic, dental and maxillofacial applications. HAp is a similar to structural and chemical resemblance to teeth and bone due to its key inorganic phosphate. HAp is a most prominent bio-material which discovers use as a teeth or bone substitution and regeneration and hard tissue repair (Orlovskii *et al.*, 2002; Huang *et al.*, 2011).

Key properties

- HAp decomposition temperature are very high; about 800–1200°C (depends upon its stoichiometry) that's why it is best suitable for creating/developing biomedical scaffolds/inserts.
- HAp is able to integrate in teeth/bone structure and helps in teeth/bone ingrowth, without dissolving and break down (i.e., HAp is bio-compatible, and bioactive material).
- Generally, HAp made scaffolds/inserts are biocompatible and bioactive as well as open porous structure which is best suitable for bone regeneration.

Applications

• Bio-ceramic Coating

HAp coating are frequently used to polymeric/metallic inserts to modify the surface properties. In this way the body sees HAp type material which it is easy to accept. Without coating the body would see as a external body and work as like surrounding tissue isolate them. To date, the main commercially acknowledged technique for applying HAp coatings to polymeric/metallic inserts is plasma showering.

• Bone Fillers

HAp might be utilized in different forms, for example powders, porous blocks or beads to fill bone deformities or voids. The bone filler will give scaffolds/inserts and empower the bone filling rate of the void by normally bone forming and gives another option to bone regrowth. It will treated turn out to be a piece of the bone structure and it will minimize the reassemble/regeneration/regrowth compared to the circumstance, if no bone filler was utilized.

Chitosan (CS)

CS is a sugar that is gotten from the hard external skeleton of shellfish, including crab, lobster, and shrimp. It is utilized for pharmaceutical/biomedical applications. Chitosan is utilized to treat corpulence, cholesterol, and Crohn's health problem. CS

used to treat issues that kidney failure patients on dialysis frequently confront, including cholesterol problem, anaemia, loss of strength and appetite, and sleeping problem (insomnia). A few people apply chitosan straightforwardly to their gums to treat aggravation that can prompt tooth misfortune (periodontitis), or bite gum that contains chitosan to counteract “cavities” (dental caries). With an end goal to enable “giver to tissue” modify itself, plastic specialists some of the time apply chitosan specifically to places from which they have taken tissue to be utilized somewhere else. In pharmaceutical assembling, CS is utilized as filler in tablets; as a transporter in controlled-discharge drugs; to enhance the way certain medications terminate.

Table 1 shows the principal characteristics and their potential applications in biomedical field of CS material. Today CS is one of the most usable materials and shows great current interest in biomedical applications. CS is one and only pseudo-natural cationic polymer. Its character (cationic) is unique. Its main applications in medical field are much diversified (as like; Dental implants, artificial skin, contact lenses, regeneration/regrowth of bone/teeth).

Methods

Today biocompatible and biodegradable scaffolds/inserts are most trending area/topic for biomedical or for research in the field of tissue/bone engineering application. HAp is one of the most useful materials (HAp is bioactive and biocompatible) in the field of tissue/bone engineering applications. Bone/tissue regeneration is the main properties of HAp. In this article, HAp is reinforced with biocompatible and biodegradable PLA (polymer) and CS (composite) in the accurate proportion (by weight) that non-toxic feed stock filament are to be prepared for the fabrication of non-toxic biocompatible, biodegradable and bioactive scaffolds/inserts using open source FDM (Singh *et al.*, 2018a,b). **Fig. 2** shows step wise procedure for fabrication/development of biodegradable, biocompatible and bioactive scaffolds/inserts using HAp, PLA and CS.

Experimentation

In the pilot experimentation, an effort has been made to prepare/find the best composition material (which is biocompatible, biodegradable, bioactive and non-toxic) for development of open porous biodegradable biomedical scaffold/implants/inserts in tissue/bone engineering applications. In pilot experimentation at first, we select the different composition of polymer (PLA) which is reinforced with biocompatible and bioactive composites (HAp and CS) in different compositions (shows in **Table 2**). After that some experimental study was conducted to understand MFI, flow continuity for wire drawing, dimensional accuracy, tensile properties, thermal properties and SEM analysis and finally best composition/proportion of reinforcement has been established for drawing the feed stock filament by using TSE. After parametric optimizations of TSE process and open source FDM functional prototypes have been printed. For TSE process input parameter selected are; temperature of TSE barrel, revolution of TSE screw and applied dead weight during experimentation and in open source FDM, input parameter selected are; layer thickness of single layer of sample (for tensile and flexural samples), deposition angle of polymer material and fill density of sample.

Rheological Properties

In the pilot experimentation at first different material compositions/proportions were selected (based upon literature review). Out of selected compositions/proportions (available in literature), eight different composition (by weight percentage) were shortlisted (based upon applications in TE) to determine the best composition/proportion of materials. The experiment was conducted to check the continuous flow ability and MFI value per 10 min. **Table 2** shows the different composition ratio of PLA-HAp-CS and its MFI value according to ASTM standard. The composite material is put into the pre-heated barrel of MFI tester. The weight and temperature as per the ASTM standard (D 1238-95) was put on the piston to expel the molten material from barrel and thereby made to exit out of die opening as extruded and weighed to find MFI in terms of gm/10min.

Table 1 Properties of CS according to use in biomedical applications

<i>Principal characteristics</i>		<i>Potential biomedical applications</i>
Biodegradable	→	Dental implants
Nontoxic, biological tolerance	→	Time release drugs for animals and humans
Hydrolyzed by lyzosome wound healing properties efficient against bacteria, fungi, viruses	→	Encapsulating material
Biocompatible	→	Surgical stitches
Film forming	→	Rebuilding/regrowth of bone
Renewable	→	Artificial skin
Hydrating agent	→	Corneal contact lenses

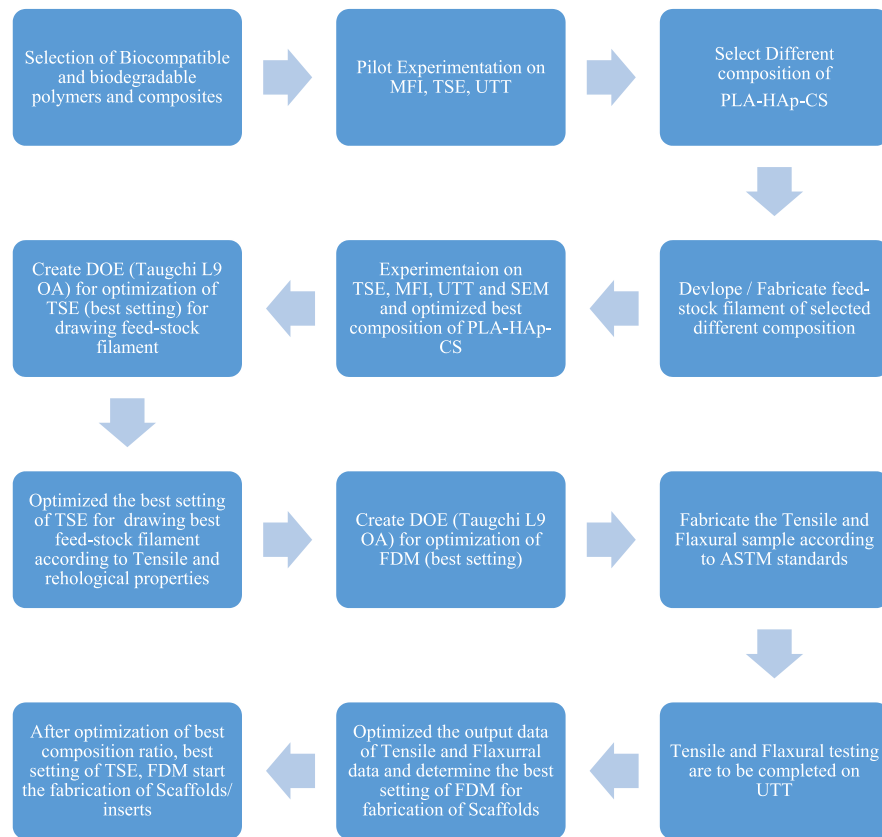

Fig. 2 Step wise procedure for fabrication of biodegradable scaffolds/inserts using HAp, CS, PLA.

Table 2 Rheological and flow-ability of different compositions of PLA-HAp-CS

S. no.	Material composition (PLA-HAp-CS) (by wt%)	MFI (gm/10 min)	Flow continuity	Remarks
1.	100-0-0	13.52	Yes	Adequate
2.	84-4-12	10.512	Yes	Adequate
3.	80-8-12	9.015	Yes	Adequate
4.	76-12-12	3.125	No	Not suitable
5.	91-8-1	12.352	Yes	Adequate
6.	90-8-2	11.575	Yes	Adequate
7.	89-8-3	7.474	No	Not suitable
8.	88-8-4	4.465	No	Not suitable

Dimensional and Tensile Properties

Based upon **Table 2**, 04 material compositions/proportions were selected to analyze dimensional and tensile properties (see **Fig. 3**).

After selection of four best compositions/proportions of feed stock filament, polymer matrix composite was processed on TSE (make: HAAKE Mini CTW, Germany). After the preparation of feed stock filament dimensional accuracy was checked by Mitutoyo's absolute digimatic micro-meter (as per ISO3611-1978) having accuracy up to 0.001 mm and tensile test on UTT.

Thermal Properties

In this experimentation part all four compositions/proportions of PLA-HAp-CS ready feed stock filament were analysed from thermal stability view point. Thermal analysis for all four compositions/proportions was carried out by METTLER TOLEDO, Model DSC3; Swiss make with STAR[®] (SW 14.00) software in N₂ gas environment. In this experimentation part glass transition temperature (°C), crystallization (%) and melting temperature (°C) were determined. **Fig. 4** shows the graphical as well as tabular data of thermal analysis of all four compositions of PLA-HAp-CS reinforced materials.

Fig. 3 Graphical representation of dimensional and tensile properties with different composition of PLA-HAp-CS.

Fig. 4 Graphical representation of thermal properties of PLA-HAp-CS composites.

SEM Analysis

Based upon mechanical properties (see Fig. 3) and thermal analysis (see Fig. 4) PLA-HAp-CS with composition/proportion as 91%-8%-1% has been selected for further analysis as it has better mechanical properties and acceptable crystallization (%). Further for SEM analysis photographs were taken by SEM (Model no. JEOL JSM-6510LV SEM, Japan). Fig. 5 shows SEM image of composite material 91%-8%-1%, which shows open porous and fibrous structure suitable for TE applications.

DOE and Output of Tensile Test for Best Setting of TSE for Feed Stock Filament

After determining the best composition of PLA-HAp-CS materials; next step was to determine the best setting of TSE for preparation/drawing best feed stock filament according to tensile strength. The feed stock filament has been prepared as per Taguchi L9 ($\hat{3}3$) OA. Table 3 shows the DOE based upon Taguchi L9 ($\hat{3}3$) OA which was 9 runs of experimentation. A total of 9 sets of specimen (feedstock filament) has been prepared by using different factors (namely; Temperature of barrel, revolution speed of screw and dead weight applied during experimentation) and total of 27 (9×3) experiments were conducted to reduce the effect of human variations and environmental effect etc. Fig. 6 shows that 3D view of TSE.

Table 3 shows that DOE and its output results of tensile results (Strength at Peak (MPa) and Peak Load (N)) which was obtained on the UTT by testing all set of feed stock filament wire which was made by using TSE according to Taguchi L9 OA. In Table 3 SNRA for strength at peak and peak load are to be shown which was determine/obtained by Minitab 17.0 software.

DOE of FDM for Fabrication of Scaffolds/Inserts for Tissue/Bone Engineering Applications

According to Table 3 determine the best setting of TSE for drawing/preparation of best feed stock filament according to tensile strength. Before the preparation of scaffolds/inserts/implants for tissue/bone engineering application open source FDM must optimized; for optimization of FDM the DOE are chosen as Taguchi L9 ($\hat{3}3$) OA. There are total two types of sample tensile and flexural sample (according to ASTM standards) are to be prepared according to same DOE which was designed as Taguchi L9 ($\hat{3}3$) OA. A total of 9 sets of tensile and 9 sets of flexural specimen (ASTM standards) has been prepared by using different input factors (namely; Layer thickness of sample (mm)), deposition angle ($^{\circ}$ C) of extruded material through FDM nozzle and fill density (%) of both sample. Table 4 shows the DOE of open source FDM for fabrication/preparation of tensile and flexural sample according to ASTM standards.

After preparation of tensile and flexural sample (ASTM standards) according to DOE Taguchi L9 OA total 18 sample (9 samples for tensile and 9 samples for flexural) are to be prepared on open source FDM. In **Fig. 8 (a)** shows that 9 fabricated sample of tensile sample according to DOE and **Fig. 8 (b)** shows that 9 fabricated sample of flexural sample according to DOE.

Fabricated parts of tensile and flexural sample are to be tested on UTT for tensile test and 3 point bending test. **Fig. 9** shows the 3D view of UTT (manufacturer; SHANTA ENGINEERING, Ludhiana) during tensile testing of tensile sample. Also close view/ exploded view clearly shows the setup of tensile testing. 3-point bending test is also performed on UTT only setup and some software setting were changed according to requirement.

Result and Discussions

Rheological Properties

After successful runs of pilot experimentation and literature review, it found that HAp is most suitable material for fabrication/development of scaffolds/inserts for TE/biomedical applications. HAp are reinforced with PLA and CS in some proportion (shows in **Table 2**). In MFI testing found that five out of eight composition are most suitable according to continuous flow ability test; In which one composition is pure PLA that is used for comparison are to be neglected because pure PLA are not used for development of scaffolds/inserts. So finally only four samples are to be selected for further testing for best composition selection. In **Table 2** MFI value of all the samples are to be shown.

Dimensional and Tensile Properties

After the selection of four compositions according to MFI and continuous flow ability are to be used for preparation of four feed stock filament on TSE. The main reason for fabrication of feed stock filament is fabrication/development of scaffolds/inserts on FDM machine. So, FDM input wire are required some special requirement (equal and in range diameter of feed stock filament). In **Fig. 3** shows that graphical representation of all four feed stock filament average diameter and it was found that all four sample according to dimensional analysis view are suitable for use. In **Fig. 3** tensile test (peak strength) result are to be obtained from UTT. In this result it conclude that after increasing of HAp and CS material in PLA polymers the strength of feed stock filament are to be decreased. So higher HAp and CS ratio for reinforcement in PLA polymers are not suitable.

Fig. 8 Fabricated tensile and flexural sample on FDM with reinforcement of PLA-HAp-CS (91-8-1). (a) Fabricated tensile sample (ASTM standards) on FDM, (b) Fabricated flexural sample (ASTM standards) on FDM.

Fig. 9 3D view of UTT and operational view of tensile testing of tensile sample (ASTM standards).

Thermal Properties

In the thermal analysis experimentation are done on METTLER TOLEDO DSC. In this, all four feed stock filaments are cut in very small piece (3–10 mg) and two heating and cooling cycles are to be run in the presence of N_2 gas environment. In [Fig. 4](#) all thermal analysis data (glass transition temperature, percentage of crystallinity and melting temperature) are to be written and shows in graphical form. At first glass transition temperature data are to be checked and found no more significant difference so all the wire are suitable and same results are also shows in the case of melting temperature. At last crystallinity (percentage) are checked and found that 91-8-1 (PLA-HAp-CS) composition are less crystallinity which was best suited for TE/biomedical applications. 80-8-12 (PLA-HAp-CS) composition are also less crystallinity but due to less tensile strength.

SEM Analysis

Finally, for selection of best composition of PLA-HAp-CS SEM test performed on two composition (91-8-1 and 90-8-2). For SEM analysis at first gold plating are covered on sample and in vacuum chamber at different pixel, microphotographs are to be taken. [Fig. 5](#) shows the both microphotographs and it concluded that both the sample structure are open porous structure, which was good for growth of cells and are suitable in bio-medical application and fabrication of scaffolds/inserts for TE. The porous structure of an inserts provides channels for tissue ingrowth. Porous materials introduced to obtain biological fixation and improve longevity of orthopaedic inserts. Due to several clinically important disadvantages of dense biomaterials (polymeric), such as a high value of elasticity modulus, the fabrication of porous structures by powder metallurgy, foaming technologies, as well as AM methods have

been widely developed in the last decades to overcome the limitations. In addition, porosity enhances the biological interlock between implant and bone.

Tensile Testing for Best Setting of TSE for Feed Stock Filament

After the selection of best composition of PLA-HAp-CS DOE prepared this are shows in [Table 3](#). This test are to be perform for optimizing the TSE best setting for fabrication of feed stock filament of best composition (91-8-1 (PLA-HAp-CS)).

● For Strength at Peak

[Fig. 10](#) shows the main effects plot for signal-to-noise ratios (SNRA) for strength at peak output parameter (for larger the better type case).

As observed in [Fig. 10](#) it was suggested that best setting according to peak strength are 190°C of barrel temperature and screw speed are best suitable are 140 rpm and applied dead weight are best suited are 12 kg. [Table 5](#) shows response table for SNRA for larger is better type for strength at peak.

As shown in [Table 6](#), percentage error was 0.99%. It shows that the model has a higher degree of accuracy. Further, it was observed that temperature of barrel and dead weight are the only significant parameters, which contributes 36.25% and 62.44%, respectively and rotational speed of screw was not significant and have less percentage contribution of 0.32%. Finally, the calculated value for strength at peak is 5.00 MPa, which is close to the experimentally observed value ([Table 7](#)).

For optimization following formula based upon Taguchi L9 OA design has been used:

$$\eta_{\text{opt}} = m + (m_{A3} - m) + (m_{B2/3} - m) + (m_{C3} - m)$$

Where,

m is the overall mean of S/N data,

m_{A3} is the mean of S/N data for Temperature of barrel at level 3,

$m_{B2/3}$ is the mean of S/N data for RPM at level 2/3,

and, m_{C3} is the mean of S/N data for Dead weight at level 3.

$$y_{\text{opt}}^2 = (1/10)^{\eta_{\text{opt}}/10} \quad \text{for properties, lesser is better}$$

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10} \quad \text{for properties, larger is better}$$

Calculation,

Overall mean of S/N ratio (m) was taken from Minitab software.

$$m = 11.71$$

Now from response table of signal to noise ratio, $m_{A3} = 12.79$, $m_{B2/3} = 11.76$ and $m_{C3} = 12.86$.

From here,

$$\eta_{\text{opt}} = 11.71 + (12.79 - 11.71) + (11.76 - 11.71) + (12.86 - 11.71)$$

$$\eta_{\text{opt}} = 13.99 \text{ db}$$

Fig. 10 Main effect plots for SNRA for strength at peak.

Table 5 Response table for SNRA larger is better for strength at peak (feed stock filament)

Level	Temperature	RPM	Dead weight
1	11.15	11.61	10.42
2	11.19	11.76	11.85
3	12.79	11.76	12.86
Delta	1.63	0.16	2.44
Rank	2	3	1

Table 6 Analysis of variance for strength at peak (feed stock filament)

Source	DF	Seq SS	Adj SS	Adj MS	F-value	P-value	%age contribution
Temperature	2	5.2203	5.2203	2.61014	36.81	0.026	36.25
RPM	2	0.0456	0.0456	0.02280	0.32	0.757	0.32
Dead weight	2	8.9917	8.9917	4.49584	63.41	0.016	62.44
Error	2	0.1418	0.1418	0.07091			0.99
Total	8	14.399					

Source: Abbreviations: Adj.MS, adjacent mean of squares; Adj.SS, adjacent sum of square; DF, degree of freedom; F, fishers value; P, probability; Seq.SS, sum of square.

Table 7 Response table for SNRA larger is better for peak load (feed stock filament)

Level	Temperature	RPM	Dead weight
1	17.68	17.98	16.69
2	17.66	18.36	18.38
3	19.20	18.21	19.48
Delta	1.53	0.38	2.79
Rank	2	3	1

Now,

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$$

$$y_{\text{opt}}^2 = (10)^{13.99/10}$$

$$y_{\text{opt}} = 5.00 \text{ MPa}$$

Finally, the calculated optimum value for strength at peak is 5.00 MPa.

● For Peak Load

Fig. 11 shows the main effects plot for SNRA for strength at peak output parameter (for larger the better type case).

As shown in **Table 8**, percentage error was 1.20%. It shows that the model has a higher degree of accuracy. Further, it was observed that temperature of barrel and dead weight are the only significant parameters, which contribute 27.41%, and 70.09% respectively and rotational speed of screw was not significant and have less percentage contribution of 1.28%.

For optimization following formula based upon Taguchi L9 OA design has been used:

$$\eta_{\text{opt}} = m + (m_{A3} - m) + (m_{B2} - m) + (m_{C3} - m)$$

Where,

m is the overall mean of S/N data,

m_{A3} is the mean of S/N data for Temperature of barrel at level 3,

m_{B2} is the mean of S/N data for RPM at level 2,

and, m_{C3} is the mean of S/N data for Dead weight at level 3.

$y_{\text{opt}}^2 = (1/10)^{\eta_{\text{opt}}/10}$ for properties, lesser is better

$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$ for properties, larger is better

Calculation,

Overall mean of S/N ratio (m) was taken from Minitab software.

$$m = 18.18$$

Now from response table of signal to noise ratio, $m_{A3} = 19.20$, $m_{B2} = 18.36$ and $m_{C3} = 19.48$.

Fig. 11 Main effect plots for SNRA for peak load.

Table 8 Analysis of variance for peak load (feed stock filament)

Source	DF	Seq SS	Adj SS	Adj MS	F-value	P-value	% age contribution
Temperature	2	4.6459	4.6459	2.3229	22.73	0.042	27.41
RPM	2	0.2162	0.2162	0.1081	1.06	0.486	1.28
Dead weight	2	11.8841	11.8841	5.9421	58.14	0.017	70.09
Error	2	0.2044	0.2044	0.1022			1.20
Total	8	16.9506					

From here,

$$\eta_{\text{opt}} = 18.18 + (19.20 - 18.18) + (18.36 - 18.18) + (19.48 - 18.18)$$

$$\eta_{\text{opt}} = 20.68\text{db}$$

Now,

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$$

$$y_{\text{opt}}^2 = (10)^{20.68/10}$$

$$y_{\text{opt}} = 10.81 \text{ N}$$

Finally, the calculated optimum value for peak load is 10.81 N.

Based upon peak values in Fig. 11, the confirmatory experiment for peak load was conducted and observed value was 10.89 N (which is very close to the calculated value).

Tensile and Flexural Testing of Fabrication of Scaffolds/Inserts for Tissue/Bone Engineering Applications

After the optimization of best setting of TSE feed stock filaments are prepared with composition of PLA-HAp-CS (91-8-1) are prepared and for fabrication of scaffolds/inserts/implants on open source FDM setting must be optimized. So DOE according to Taguchi L9 OA are to be designed which is shown in Table 4. Scaffolds must be good strength in view of tensile and flexural side; so both sample are to be formed according to this DOE.

Tensile properties according to ASTM standards with composition of PLA-HAp-CS

Table 9 shows that all the output data of tensile test and its SNRA data for tensile specimens (According to ASTM standards) (Table 10).

• For Break Load

Fig. 12 shows the main effects plot for SNRA for break load for tensile specimen output parameter (for larger the better type case).

Table 10 Response table for SNRA larger is better for break load (Tensile Specimen)

Level	Layer thickness	Deposition angle	Infill density
1	54.69	53.67	49.63
2	51.81	53.66	53.78
3	53.09	52.26	56.18
Delta	1.53	0.38	2.79
Rank	2	3	1

**Fig. 12** Main effect plots for SNRA for break load.

As shown in Table 11, percentage error was 1.20%. It shows that the model has a higher degree of accuracy. Further, it was observed that Infill density is the only significant parameter which contributes 76.69% and layer thickness and deposition angle was not significant and have less percentage contribution of 14.53%, 4.63%, respectively.

For optimization following formula based upon Taguchi L9 OA design has been used:

$$\eta_{\text{opt}} = m + (m_{A1} - m) + (m_{B1} - m) + (m_{C3} - m)$$

Where,

m is the overall mean of S/N data,

m_{A1} is the mean of S/N data for Layer thickness at level 1,

m_{B1} is the mean of S/N data for Deposition angle at level 1,

and, m_{C3} is the mean of S/N data for Infill density at level 3.

$$y_{\text{opt}}^2 = (1/10)^{\eta_{\text{opt}}/10} \text{ for properties, lesser is better}$$

Table 11 Analysis of variance for break load (Tensile Specimen)

Source	DF	Seq SS	Adj SS	Adj MS	F-value	P-value	%age contribution
Layer thickness	2	12.473	12.473	6.236	3.50	0.222	14.53
Deposition angle	2	3.977	3.977	1.988	1.12	0.472	4.63
Infill density	2	65.838	65.838	32.919	18.48	0.051	76.69
Error	2	3.562	3.562	1.781			1.20
Total	8	85.850					

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10} \text{ for properties, larger is better}$$

Calculation,

Overall mean of S/N ratio (m) was taken from Minitab software.

$$m = 53.20$$

Now from response table of signal to noise ratio, $m_{A3} = 54.69$, $m_{B2} = 53.67$ and $m_{C3} = 56.18$.

From here,

$$\eta_{\text{opt}} = 53.20 + (54.69 - 53.20) + (53.67 - 53.20) + (56.18 - 53.20)$$

$$\eta_{\text{opt}} = 58.14 \text{ db}$$

Now,

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$$

$$y_{\text{opt}}^2 = (10)^{58.14/10}$$

$$y_{\text{opt}} = 807.23 \text{ N}$$

Finally, the calculated optimum value for break load is 807.23 N., which is close to the experimentally observed value.

● For Break Elongation

Fig. 13 shows the main effects plot for SNRA for break elongation for tensile specimen output parameter (for larger the better type case) (**Table 12**).

As shown in **Table 13**, percentage error was 0.69%. It shows that the model has a higher degree of accuracy. Further it was observed that Infill density and layer thickness are the significant parameters which contribute 71.42%, 26.58% and deposition angle was not significant and have less percentage contribution of 1.31%.

For optimization following formula based upon Taguchi L9 OA design has been used:

$$\eta_{\text{opt}} = m + (m_{A1} - m) + (m_{B2} - m) + (m_{C3} - m)$$

Where,

m is the overall mean of S/N data,

m_{A1} is the mean of S/N data for Layer thickness at level 1,

m_{B2} is the mean of S/N data for Deposition angle at level 2,

and, m_{C3} is the mean of S/N data for Infill density at level 3.

$$y_{\text{opt}}^2 = (1/10)^{\eta_{\text{opt}}/10} \text{ for properties, lesser is better}$$

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10} \text{ for properties, larger is better}$$

Calculation,

Overall mean of S/N ratio (m) was taken from Minitab software.

$$m = 14.20$$

Now from response table of signal to noise ratio, $m_{A1} = 16.51$, $m_{B2} = 14.63$ and $m_{C3} = 17.97$.

From here,

$$\eta_{\text{opt}} = 14.20 + (16.51 - 14.20) + (14.63 - 14.20) + (17.97 - 14.20)$$

$$\eta_{\text{opt}} = 20.71 \text{ db}$$

Now,

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$$

$$y_{\text{opt}}^2 = (10)^{20.71/10}$$

Fig. 13 Main effect plots for SNRA for break elongation.

Table 12 Response table for SNRA larger is better for break elongation (Tensile Specimen)

Level	Layer thickness	Deposition angle	Infill density
1	16.51	13.74	11.88
2	12.83	14.63	12.76
3	13.27	14.25	17.97
Delta	3.68	0.88	6.09
Rank	2	3	1

Error	2	0.6267	0.6267	0.3134			0.69
Total	8	90.9389					

$$y_{\text{opt}} = 10.852 \text{ mm}$$

Finally, the calculated optimum value for break elongation is 10.852 mm. That is close to the experimentally observed value.

- **For Young's Modulus**

Fig. 14 shows the main effects plot for SNRA for Young's modulus for tensile specimen output parameter (for larger the better type case) (**Table 14**).

As shown in **Table 15**, percentage error was 2.87%. It shows that the model has a higher degree of accuracy. Further it was observed that layer thickness is the only significant parameter, which contribute 54.85% and deposition angle and infill density was not significant and have less percentage contribution of 25.12% and 17.16%, respectively.

For optimization following formula based upon Taguchi L9 OA design has been used:

$$\eta_{\text{opt}} = m + (m_{A1} - m) + (m_{B1} - m) + (m_{C1} - m)$$

Where,

m is the overall mean of S/N data,

m_{A1} is the mean of S/N data for Layer thickness at level 1,

m_{B1} is the mean of S/N data for Deposition angle at level 1,

Fig. 14 Main effect plots for SNRA for Young's modulus.

Table 14 Response table for SNRA larger is better for Young's Modulus (Tensile Specimen)

Level	Layer thickness	Deposition angle	Infill density
1	46.39	46.91	45.69
2	45.91	42.23	44.62

Total	8	157.151					

and, m_{C1} is the mean of S/N data for Infill density at level 1.

$$y_{\text{opt}}^2 = (1/10)^{\eta_{\text{opt}}/10} \text{ for properties, lesser is better}$$

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10} \text{ for properties, larger is better}$$

Calculation,

Overall mean of S/N ratio (m) was taken from Minitab software.

$$m = 43.97$$

Now from response table of signal to noise ratio, $m_{A1} = 46.39$, $m_{B1} = 46.91$ and $m_{C1} = 45.69$.

From here,

$$\eta_{\text{opt}} = 43.97 + (46.39 - 43.97) + (46.91 - 43.97) + (45.69 - 43.97)$$

$$\eta_{\text{opt}} = 51.05\text{db}$$

Now,

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$$

$$y_{\text{opt}}^2 = (10)^{51.05/10}$$

$$y_{\text{opt}} = 356.86 \text{ MPa}$$

Finally, the calculated optimum value for Young's modulus is 356.86 MPa. Which is close to the experimentally observed value.

Flexural properties according to ASTM standards with composition of PLA-HAp-CS

Table 16 shows that all the output data of 3-point bending test and its SNRA data for flexural specimens (According to ASTM standards).

• For Break Load

Fig. 15 shows the main effects plot for SNRA for break load of flexural specimen as output parameter (for larger the better type case).

Table 17 shows that in response table and ranking table for SNRA larger is better for break load (Flexural specimen).

As shown in **Table 18**, percentage error was 7.65%. It shows that the model has a higher degree of accuracy. Further, it was observed that Infill density is the only significant parameter which contributes 81.02% and layer thickness and deposition angle was not significant and have less percentage contribution of 3.99% and 7.34%, respectively.

For optimization following formula based upon Taguchi L9 OA design has been used:

$$\eta_{\text{opt}} = m + (m_{A3} - m) + (m_{B2} - m) + (m_{C3} - m)$$

Where,

m is the overall mean of S/N data,

m_{A3} is the mean of S/N data for Layer thickness at level 3,

m_{B2} is the mean of S/N data for Deposition angle at level 2,

and, m_{C3} is the mean of S/N data for Infill density at level 3.

$$y_{\text{opt}}^2 = (1/10)^{\eta_{\text{opt}}/10} \quad \text{for properties, lesser is better}$$

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10} \quad \text{for properties, larger is better}$$

Calculation,

Overall mean of S/N ratio (m) was taken from Minitab software.

$$m = 53.76$$

Now from response table of signal to noise ratio, $m_{A3} = 54.34$, $m_{B2} = 54.35$ and $m_{C3} = 55.78$.

From here,

$$\eta_{\text{opt}} = 53.76 + (54.34 - 53.76) + (54.35 - 53.76) + (55.78 - 53.76)$$

$$\eta_{\text{opt}} = 56.95 \text{ db}$$

Now,

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$$

$$y_{\text{opt}}^2 = (10)^{56.95/10}$$

$$y_{\text{opt}} = 703.88 \text{ N}$$

Finally, the calculated optimum value for break load is 703.88 N. Based upon peak values in **Fig. 15**, the confirmatory experiment for break load was conducted and observed value was 689.53 N (which is very close to the calculated value).

Table 16 Output of tensile sample and its SNRA data

● For Strength at peak

Fig. 16 shows the main effects plot for SNRA for strength at peak of flexural specimen as output parameter (for larger the better type case).

Table 19 shows that in response table and ranking table for SNRA larger is better for strength at peak (Flexural specimen).

As shown in **Table 20**, percentage error was 7.65%. It shows that the model has a higher degree of accuracy. Further it was observed that Infill density is the only significant parameter which contributes 81.02% and layer thickness and deposition angle were not significant and have less percentage contribution of 3.99% and 7.34%, respectively.

For optimization following formula based upon Taguchi L9 OA design has been used:

$$\eta_{\text{opt}} = m + (m_{A3} - m) + (m_{B2} - m) + (m_{C3} - m)$$

Where,

m is the overall mean of S/N data,

m_{A3} is the mean of S/N data for Layer thickness at level 3,

m_{B2} is the mean of S/N data for Deposition angle at level 2,

and, m_{C3} is the mean of S/N data for Infill density at level 3.

$$y_{\text{opt}}^2 = (1/10)^{\eta_{\text{opt}}/10} \quad \text{for properties, lesser is better}$$

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10} \quad \text{for properties, larger is better}$$

Calculation,

Fig. 16 Main effect plots for SNRA for strength at peak (flexural specimen).

Table 19 Response table for SNRA larger is better for strength at peak (Flexural Specimen)

Level	Layer thickness	Deposition angle	Infill density
1	51.33	51.67	48.89
2	51.05	52.07	52.05
3	52.06	50.69	53.50
Delta	1.01	1.38	4.61
Rank	3	2	1

Table 20 Analysis of variance for strength at peak (Flexural Specimen)

Source	DF	Seq SS	Adj SS	Adj MS	F-Value	P-Value	% age Contribution
Layer thickness	2	1.644	1.644	0.8219	0.52	0.657	3.99
Deposition angle	2	3.024	3.024	1.5120	0.96	0.510	7.34
Infill density	2	33.366	33.366	16.6831	10.60	0.086	81.02
Error	2	3.149	3.149	1.5745			7.65
Total	8	41.183					

Overall mean of S/N ratio (m) was taken from Minitab software.

$$m = 51.48$$

Now from response table of signal to noise ratio, $m_{A3} = 52.06$, $m_{B2} = 52.07$ and $m_{C3} = 53.50$.

From here,

$$\eta_{\text{opt}} = 51.48 + (52.06 - 51.48) + (52.07 - 51.48) + (53.50 - 51.48)$$

$$\eta_{\text{opt}} = 54.67 \text{ db}$$

Now,

$$y_{\text{opt}}^2 = (10)^{\eta_{\text{opt}}/10}$$

$$y_{\text{opt}}^2 = (10)^{54.67/10}$$

$$y_{\text{opt}} = 541.38 \text{ MPa}$$

Finally, the calculated optimum value for Strength at peak is 541.38 MPa. Based upon peak values in **Fig. 16**, the confirmatory experiment for break load conducted and observed value was 532.56 MPa (which is very close to the calculated value).

Conclusion

Following are the conclusions from present case study:

- HAp, PLA and CS are one of the best suitable materials for fabrication of biocompatible/biodegradable/bioactive scaffolds/inserts for TE/biomedical applications. HAp is best suited material because its characteristic is 99% similar to bone and teeth. CS is bioactive polymers which ignite the tissue in growth rate and PLA is biocompatible as well as biodegradable polymer.
- For fabrication of feed stock filament of different compositions/proportions of PLA-HAp-CS experimentation based study was conducted based upon thermal analysis, MFI, tensile testing, continuous flow ability and dimensional analysis. It was observed that best composition/proportion selected is 91%-8%-1%.
- In SEM analysis of feed stock filament it has been ascertained that the specimens/functional prototype prepared are structurally suitable for repair/regeneration of bone/fractured bone because the internal structure of the sample is fibrous, open and porous. The porous structure of an implant provides channels for bone ingrowth. In addition, porosity enhances the biological interlock between implant and bone.
- Based upon TSE optimization for determining the best setting of factors is barrel temperature 190°C, rotational speed of screw are 140 rpm and applied load 12 kg for fabrication of feed stock filament.
- Based upon FDM optimization for determining the best setting for tensile properties are layer thickness 0.2 mm, infill density of sample is 100 % and deposition angle is 45° and best setting of FDM for flexural test are obtained as layer thickness is 0.3 mm, infill density of sample is 100 % and deposition angle is 45°.

District Heating Systems From Environmental Waste

Dalibor Petković, University of Niš, Pedagogical Faculty in Vranje, Partizanska, Vranje, Serbia

© 2020 Elsevier Inc. All rights reserved.

Introduction

District heating systems (DHS) are based on production of heat and distribution of produced heat to consumers. Every DHS is comprised of three basic elements: heat source, distribution network and consumers. In order to be competitive with individual heating systems, DHS must use one of the five suitable strategic local energy resources: useful waste heat from thermal power stations (cogeneration); heat obtained from refuse incineration; useful waste heat from industrial processes; natural geothermal heat sources and fuels difficult to manage, such as wood waste, peat, straw, or olive stones (Werner, 2004) and have advanced control which will lower operation and distribution costs.

One of the first systematic analyses of heat load in whole district systems was provided (Werner, 1984) where comprehensive study of factors affecting the value and character of heat load was performed. Further analysis of heat load in district heating system was undertaken (Madsen *et al.*, n.d.) where different nonparametric and parametric methods and models were developed and tested with sampled data from Esbjerg district heating system. Review of parametric, non- and semi-parametric methods and models for heat load was presented in Nielsen and Madsen (2000).

Environmental waste could have high potential as resource for district heating system. In this study we analyzed potential of designing of district heating systems from environmental waste.

Literature Overview

Data centers seek solutions to increase energy efficiency and lower costs by novel methods. Waste heat utilization is considered to be one of the major trends in the near future, especially in the Nordic countries, where heat demand is high. In this paper, waste heat utilization was analyzed from the perspectives of both the data center and district heating network operators (Wahlroos *et al.*, 2017). District Heating System (DHS) using waste heat is highlighted as an attractive solution. Supported by technological assessment and emerging concepts of Industrial-Urban Symbiosis (I-US), in study (Dou *et al.*, 2016) was combined the system development of DHS and land use scenarios into a symbiotic design based on inventory survey and geographic database, and conducts a cost-benefit analysis to scientifically and quantitatively evaluate the effects brought from land-use policies. The refurbishment of existing buildings is often considered a way to reduce energy use and CO₂ emissions in the building stock. In study (Lidberg *et al.*, 2017) was analyzed the primary energy and CO₂ impact of refurbishing a multi-family house with different refurbishment packages, given various district heating systems. To meet the district heating demands and recover the industrial waste heat simultaneously, high-efficiency centrifugal heat pumps are applied for district heating and heat recovery (Hu *et al.*, 2017). Municipal solid waste has seen increasing annual volumes for many decades in contemporary Europe and constitutes, if not properly managed, an environmental problem due to local pollution and greenhouse gas emissions. From an energy perspective, waste is also an alternative fuel for power and heat generation; energy recovery from waste represents an effective measure to reduce landfilling and avoid disposal emissions while simultaneously reducing the equivalent demand for primary energy supply (Persson and Münster, 2016). Low-grade industrial waste heat could be a considerable potential energy source for district heating, on the condition that the heat from different industrial waste heat sources is integrated properly. In study (Xia *et al.*, 2016) was considered a method for integrating low-grade industrial waste heat into a district heating system and focuses on how to

improve the outlet temperature of heat-collecting water by optimizing the heat exchange flow for process integration. District heating, the utilization of centrally produced heat for space heating and domestic hot water generation, has the potential to contribute to the eco-efficient use of energy resources in the parts of the world where space heating is needed. In literature, environmental studies on district heating mainly consider the emissions from heat generation; the environmental impact from the distribution system is seldom discussed. In paper (Fröling *et al.*, 2004) was presented a life cycle assessment of the production of district heating pipes, based on a cradle-to-gate life cycle inventory commissioned by the Swedish District Heating Association.

Methodology

Measurement and acquisition of data was performed in heating substation connected to heating plant with installed capacity of heat source (gas fired boilers) of 128 MW. The interior of heating substation is shown in Fig. 1.

Table 1 Statistical summary of gathered data

Heat load parameters	Minimum value	Maximum value	Mean	Median
Outdoor temperature [°C]	− 10.60	4.40	− 1.19	− 0.30
Primary supply temperature [°C]	30.70	88.70	65.71	72.30
Primary return temperature [°C]	25.70	54.30	43.75	46.50
Secondary supply temperature [°C]	27.20	59.10	47.39	50.80
Secondary return temperature [°C]	20.70	49.70	41.64	44.60
Flow on primary side [m ³ /h]	0.10	7.20	6.16	6.20
Heat load [kW]	− 8.74	273.40	157.83	182.48

The heating substation is indirectly connected to district heating system and hydraulic separation is accomplished through Schmidt-Bretten plate heat exchanger, model SIGMA X13-NCL (Fig. 2). Installed capacity of heat exchanger is 650 kW.

No domestic hot water preparation is envisaged. Heat from substation is delivered across the two-pipe system to cast iron radiators in sixty apartments. Delivered heat in apartments is manually regulated and no thermostatic radiator valves exist. Additionally, there is no measurement of indoor temperature. Flow control and consequently control of delivered heat to consumers is achieved through Danfoss AVQM (DN40) motorized flow control valve (Fig. 3).

In addition to motorized control, valve has control diaphragm for mechanical flow limitation in order to limit the excessive flow in substation. Circulation of water on secondary side is performed with constant speed Grundfoss twin pump UPSD 50-180/F. Regulation of delivered heat is achieved by Danfoss ECL comfort 300 controller which is placed in control box with other electrical equipment. Controller works on weather compensation principle and controls the temperature of delivered water to consumers/secondary side through temperature control curve, according to momentary measured outside temperature. There is no feedback from indoor temperature measurement. Two additional modules are integrated in controller: ECA 84 (for measuring of delivered heat) and ECA 87 for storage of measured values. Controller was connected with HCP HAWK high speed GPRS modem for remote data transfer. Archived data, from ECA 87 module were read off regularly during the heating season. Delivered heat is regularly measured and archived through Danfoss Ultrasonic heat meter (INFOCAL 5 (Fig. 4(a)) and SONO 2500 CT (Fig. 4(b)) system plus two PT 500 (Fig. 4(c)) temperature sensors).

Results

Gathered data were sampled on 15 minutes. Preprocessing of data was not taken into consideration. The aim was in developing recursive and robust model capable of producing the on-line predictions of consumers heat load for further use in control of DH systems. Following variables were simultaneously measured:

- Outdoor temperature [°C]
- Primary supply temperature [°C]
- Primary return temperature [°C]
- Secondary supply temperature [°C]
- Secondary return temperature [°C]
- Flow on primary side [m³/h]

Heat load was calculated based on measured values of primary supply and return temperatures and flow on primary side. Summary of statistical properties of the head load parameters is provided in Table 1.

Conclusion

District heating system from environmental waste could be very attractive domain for investigation sources. Environmental waste could has high potential as resource for district heating system. In this study we analyzed potential of designing of district heating systems from environmental waste.

E-Agriculture System by Object-Oriented Approach

Dalibor Petković, University of Niš, Pedagogical Faculty in Vranje, Partizanska, Vranje, Serbia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Application of information and communication technology (ICT) in business can enhance and improve the business because ICT has many advantages for consumers and users. One of the most important sectors for ICT application is agriculture. The system is known and e-agriculture can improve the agriculture business in many directions. E-agriculture could be described as a new field on enhancement of agricultural development through ICT processes. The system enables design, development, evaluation and application of innovative ways to use ICT in agricultural domain (Behera *et al.*, 2015).

Agriculture is facing continuously new and important problems and challenges and use of Information and Communication Technologies (ICTs) can be a major intervention for more efficient agriculture (Salampasis and Theodoridis, 2013). In order to generate meaningful improvements in food security and farm incomes, there must be commensurate efforts to promote ICT-based market information along with yield-augmenting agricultural seed technologies (Kiiza and Pederson, 2012). The infiltration of new technologies in the agricultural sector is fact and results in article (Botsiou and Dagdilelis, 2013) revealed four farm's ICT profiles. China's agriculture sector has been transformed from the traditional to modern practice through the effective deployment of ICTs (Zhang *et al.*, 2016). Agricultural extension in has often been criticized for its focus on linear knowledge transfer, and limited attention to systemic approaches to service delivery but there are high expectations of new-ICTs to enhance interaction and information exchange in extension service delivery (Munthali *et al.*, 2018). Farmers have strived for better access to information and communication and rapid technological process has now lead to a variety of new ICTs, which have the potential to address the information and communication needs of farmers much faster and with far more accuracy than ever before (Daum, 2018). ICT could be used for smart agriculture and climate-smart agriculture (CSA) is widely promoted as an approach for reorienting agricultural development under the realities of climate change (Thornton *et al.*, 2018; Dunnett *et al.*, 2018; Westermann *et al.*, 2018). Within business enterprises farmers lags behind in the uptake of new information technologies for the control and automation of farming systems (Ntaliani *et al.*, 2010; Somers and Stapleton, 2015).

The main goal in the article is to enhance the role of ICT in agricultural development by providing a framework to facilitate the processes of capturing and managing in agriculture. The system could provide the basis for monitoring of development and validation of conceptual models and methodologies in agriculture business. Object-oriented approach is used for e-agriculture system modeling (Lethbridge and Laganieri, 2005; Jacobson, 1993).

Methodology

E-Agriculture System

Introduction of ICT in agriculture sector could be empower farmer with relevant and timely information about different crop variety. Also the system could be helpful for reducing of farming risks about information on weather, production and cultivation techniques, seeds and fertilizers, plant nutrients and water usage. E-agriculture can reduce knowledge gaps and to increased knowledge sharing in order to increase productivity and boosting growth.

Object-Oriented Methodology

Rational Unified Process (RUP) is an interactive methodology for the software development based on architecture and use cases. RUP methodology is based on Unified Modeling Language (UML) (Rumbaugh *et al.*, 2004). UML is used for specification, visualization, construction and documentation of the software development.

RUP methodology has control, key or critical points through the development. In the other words each phase of the RUP methodology should end by some control, key or critical points where achieved results are summed and future directions are planned based on the results. RUP methodology has artefacts (documents), models i model elements. Project requests are noted in the documents. Models are used to simplify the software architecture without unnecessary details. Model elements could help to visualize, construct and document the main structure and software behavior. Fig. 1 shows the main elements of the RUP methodology. Each phase of the RUP methodology has iteration where disciplines are considered. The disciplines are described by process flow in details. The process shows activity and roles of everyone in the project. Finally there are artefacts where one can see software documentation, software models and model elements.

RUP methodology has four main phases. The first phase is initial phase or idea inception where one needs to understand what should to do and software vision and requirements are identified. This phase includes the identification of key software actors (users) and use cases. Also there is need to identify software domain. Use case defines one sequence of an action which software performs that yields to an observable results. In the other hands one use case presents result of an action by actor (Fig. 2). Use case

Fig. 1 Elements of RUP methodology.

Fig. 2 Use case model.

Fig. 3 RUP methodology phases.

presents the main part of some complete software operation from beginning until to the end. It is used to capture the intended behavior of the system in development. By use cases models desired behavior of the system could be specified but it is not strictly this desired behavior to be carried out or implemented in the final product. Use cases models can be developed for whole system or for the part of system. Each part of system or subsystem can be developed by use cases models until the part produces some tangible amount of work and results. System complexity dictates the number of use cases. In the initial stage of system development main use cases are developed and additional use cases can be added or included when there is need for them.

The second phase is project elaboration where one needs to understand how to build the software and basic software architecture is showed in the phase. The third phase presents software construction where software testing is considered. The fourth phase presents software transition where software validation is performed. The RUP phases are shown in [Fig. 3](#).

RUP models describes software in modeling. RUP models could be business models which describes business processes and business environment, use case models which describes what software doing and software environment, projecting models which describes use cases realization as code abstraction and implementation models which presents collection of components and subsystems.

Software development process could has different problems which needs to be identifies and solved before coding and testing. In order to solve problems there is need to find the problem causes. To remove the problem causes it is suitable to use best practices. For example in order to remove the confusion in communication between team members it is suitable to use standard language UML for the software visualization, specification and documentation. There are different types of UML diagrams which can be used in the software development process. There are two main classes of the UML diagrams. These are structural and behavioral diagrams. Structural diagram presents structure of the system in passive state and behavioral diagram present the active behavior of the objects in a system or dynamical state.

Object-orientated modeling concepts are used during analyzing and modeling of the e-agriculture system. Two UML concepts are used for the modeling. The concepts are use case models with scenarios of activities and class diagram. Use case models show dynamic behavior of the software while class diagram depicts the main structure of the system in development.

Results

[Fig. 4](#) shows the main use case diagram of the e-agriculture system. As can see there are two users of the system. First of all there is forecasting platform and second there is remote sensing module. Forecasting platform is intended for collecting of ground data. The main tasks of the remote sensing module are to estimate the yield and crop area. The remote sensing module could not work without collecting the ground data.

[Fig. 5](#) shows the use case diagram for forecasting platform where can be see two additional use cases for the forecasting platform. These use cases are forecasting of wheat yield and forecasting of rice yield. There is possibility to add additional use case for another forecasting purpose.

[Tables 1](#) and [2](#) shows detail specification of use cases for forecasting of wheat yield and forecasting of rice yield.

Fig. 5 Use case diagram – Forecasting platform.

Table 1 Specification of use case: Forecasting of wheat yield

<i>Title</i>	Forecasting of wheat yield
<i>Actors</i>	Forecasting platform
<i>Trigger</i>	It starts with acquiring raw wheat data.
<i>Pre-condition</i>	Platform is properly settled.
<i>Post-condition</i>	Forecasted wheat data.
<i>Main scenario</i>	1. Platform acquires raw wheat data from ground. 2. Platform starts software for forecasting purposes. 3. Platform performs forecasting of wheat yield. 4. Platform sends forecasted data to remote sensing module.
<i>Alternative</i>	None

Table 2 Specification of use case: Forecasting of rice yield

<i>Title</i>	Forecasting of rice yield
<i>Actors</i>	Forecasting platform
<i>Trigger</i>	It starts with acquiring raw rice data.
<i>Pre-condition</i>	Platform is properly settled.
<i>Post-condition</i>	Forecasted rice data.
<i>Main scenario</i>	1. Platform acquires raw rice data from ground. 2. Platform starts software for forecasting purposes. 3. Platform performs forecasting of rice yield. 4. Platform sends forecasted data to remote sensing module.
<i>Alternative</i>	None

Conclusion

In this study was established ICT in agriculture domain in order to develop e-agriculture system and to improve life quality. The system could help farmers and investors to get relevant information regarding agriculture, crop production and etc.

Visual modeling is a way of thinking about the problems from reality. The models are used for problems understanding, for communications between team members which are included in the project, for modeling of company, for documentation preparation and for program and database design. Modeling enable better understanding of requirements, clean design and better support and maiming of the systems.

Eco Friendly Aspects in Hybridization of Friction Stir Welding Technology for Dissimilar Metallic Materials

Swarup Bag, Indian Institute of Technology Guwahati, Guwahati, India

Esther T Akinlabi, University of Johannesburg, Johannesburg, South Africa

© 2020 Elsevier Inc. All rights reserved.

Introduction

The competitive manufacturing processes enforcing eco-friendliness focuses mainly to minimize the impact on the environment and optimum utilization of the resources. The sustainable manufacturing processes are aiming at efficient utilization of the materials and energy. In view of that, continuous modification of the manufacturing processes or substitute for existing process with alternate economic processes are going on. In this aspect, friction stir welding (FSW) is one of the green manufacturing technologies that ensures zero emissions to the environment and is known as a green technology (Mishra and Ma, 2005; Nandan *et al.*, 2008). Traditional fusion welding processes i.e., mainly arc welding and laser welding require significant amount of heat that may lead to cracking and porosity during solidification. FSW is capable of joining two materials with less amount of energy consumption and is more eco-friendly as compared to conventional fusion welding technologies. FSW is recently developed solid state welding process which is intended to overcome fusion welding limitations and both similar and dissimilar combination of materials are coalesced together through plasticization of the substrate materials (Arora *et al.*, 2009a; Buchibabu *et al.*, 2017). The schematic of FSW system along with standard terminology is depicted in Fig. 1.

In general, the liquid-phase manufacturing process i.e., fusion welding process utilizes more energy because of often reaches superheated temperature and possibility of high energy loss during transformation as compared to solid state welding process. However, the optimum utilization of resources depends on nature, type, and physical properties of the materials to be joined and a close relation exists between the quality of the joint with proper choice of the parameters. The eco-friendliness includes the green and sustainability concepts pertinent to the environment degradation, minimization of required energy, control on environmental pollution, minimum production of waste, maximum recyclability of the waste products, and, models for maintenance (Narayanan and Das, 2014). Fig. 2 depicts the support triangle and its basic elements for the development of eco-friendly welding process. A green technology aims to minimize the damage to the environment as well as maximize the use of resources that leads to savings in materials and energy while benefiting the environment (Ghodrati *et al.*, 2016). The process efficiency primarily depends on proper choice of parameters along with the material combination and secondarily the technology adapted for the processing of the material. The energy efficiency is decided by the type and nature of energy source with any environmental impact and the technology used to utilize this energy. However, economic use of material and energy according to the technology always brings in forefront the savings in resources by minimizing the waste product creation as well as by reducing the environmental pollution. In the present article, the eco-friendliness is described with reference to fusion welding and FSW processes. However, hybridization of FSW not always brings the green technology in forefront like conventional FSW process. The enhanced product quality is often compromised with eco-friendliness of the process. For high melting point and high hardness materials such as steel, the classic FSW cannot be utilized in the most economical way. It is limited by the expected tool life where the tool is often subjected to high temperature, static or dynamic load, and stress at variable temperature. Even for a costly polycrystalline cubic boron nitride (PCBN) tool having high relative hardness with respect to steel, tool wear remains high and tool life may not be economical when used in conventional FSW process (Rai *et al.*, 2011; Mehta *et al.*, 2011). These factors drive to explore various auxiliary energy sources to moderate the material to be joined and lead to develop various hybrid FSW (HFSW) processes not exceeding the melting point temperature. The hybrid technology effectively decreases the tool wear and increase the tool life i.e., creates the possibility of exploring the tool in the most economical way (Yaduwanshi *et al.*, 2015a,b; Padhy *et al.*, 2015).

There is a growing interest to the industries in hybridization of welding processes to overcome certain technological difficulties arises in conventional and fundamental processes. HFSW is quite innovative joining technique that has immense potential for extending its application to different fields of industrial problems. This technique, although classic FSW is the primary process, accomplishes mainly the hindrance of conventional FSW process. As an outlying benefit, it provides significant improvements in the weld quality and efficiency of the processes in manufacturing applications. Welding of relatively harder materials as compared to Al and Zn-based soft alloys is difficult to process by FSW due to high plasticization temperature. Secondary heat sources focusing to the harder alloys during welding process would reduce the amount of work required by FSW tool during operation. This additional heat also reduces the flow stress resistance of the workpiece by softening it without affecting the FSW tool. In effect, it improves the performance of the tool and tool life as well as the weld joint quality and efficiency (Bhadeshia and DebRoy, 2009; Nandan *et al.*, 2007). However, this additional heat may affect the environment to a lesser extent since the maximum temperature remains below the melting point of the substrate material. The nature of secondary heating is contributed from several sources and is known as so called hybrid FSW process when FSW act as primary process. HFSW processes are broadly categorised as thermal energy and mechanical energy assisted FSW. Direct use of thermal energy in HFSW are supplied from electricity

Fig. 1 Schematic diagram of FSW process. Reproduced from Mishra, R.S., Ma, Z.Y., 2005. Friction stir welding and processing. Materials Science and Engineering R 50, 1–78.

Fig. 2 Basic elements of green manufacturing technology.

(Nandan *et al.*, 2007; Long and Khanna, 2005; Santos *et al.*, 2014a,b; Potluri *et al.*, 2013; Liu *et al.*, 2015a), induction (DebRoy and Bhadeshia, 2010; Grant *et al.*, 2005; Sinclair *et al.*, 2010), laser (Palm, 2004; Bang *et al.*, 2010), plasma arc (Yaduwanshi *et al.*, 2018, 2016, 2014), hot gas stream (Lotfi and Nourouzi, 2014), gas torch (Choi *et al.*, 2011) etc. Resistance heating by direct electricity and heat generation by eddy current through induction coil do not have direct impact on the environment. However, electric arc, plasma arc, and laser as secondary heat source has less impact on environment when using with hybrid FSW process since low intensity heat energy i.e., just the heating mode is used rather than the welding mode. Mechanical energy as an auxiliary source is used in ultrasound assisted FSW process. The ultrasonic vibration directly or indirectly localize the softening behaviour of the harder material without much increment in temperature as well as least effect on whole workpiece (Lai *et al.*, 2014; Shi *et al.*, 2015; Strass *et al.*, 2014a,b; Liu *et al.*, 2015b,c; Liu and Wu, 2013).

Modern digital manufacturing process relies on data and information where the concept of green and sustainable technologies has been developed. Mathematical modeling and simulation of FSW process is an alternate way to design the process with minimum utilization of the resources. It reduces the expensive experiments, formation of prototyping, several trial-and-error repetitive experiments to identify the feasible range of parameters, and the cost by reducing significant amount of time (Ulysse, 2002; Chen and Kovacevic, 2003; Buffa *et al.*, 2006; Tseng, 2006; Heurtier *et al.*, 2006; Robson *et al.*, 2007; Okuyucu *et al.*, 2007; Schmidt and Hattel, 2008; Shojaeefard *et al.*, 2013; Wang *et al.*, 2013). In general, the index of eco-friendliness is measured by considering the elements like raw material consumed, the amount, nature, and type of emissions to the environment, and the energy efficiency for a particular manufacturing process. The sustainability of a manufacturing process is generally measured by the greenhouse emissions during the process which is almost zero in case of FSW process. However, there are several other approaches to analyse the eco-friendly aspect of the FSW process. These include broadly the optimum utilization of raw materials, reduction in specific energy consumption, reduction in waste generation, reduction in emissions, maximization of recycling, and enhanced use of renewable energy (Narayanan and Das, 2014). Fig. 3 depicts the essential elements of green manufacturing technology where the expected outcome is to develop the manufacturing process in the most economical way with minimum intervention of the environment as well as improved product quality. For the development of hybrid FSW technology, the parameters like the process

Fig. 3 The elements of green manufacturing technology and the expected outcome. Reproduced from Kopac, J., 2009. Achievements of sustainable manufacturing by machining. *Journal of Achievement in Material and Manufacturing Engineering* 34, 180–187.

efficiency, optimum utilization of energy, and enhanced product quality in terms of joint strength and status of the microstructure are the measurable quantities. The present article analysed all these significant elements based on qualitative assessment of arc welding, FSW and HFSW processes.

Eco-Friendly Aspect of Fusion Welding

The welding and joining environments is very complex in nature, specifically the fusion welding where the formation of numerous gases and particulate components from flux, shielding gas and electrode-coating impacts on the environment extremely (Palani and Murugan, 2006; Vidyarthi and Dwivedi, 2016; Liu *et al.*, 2016). Modern manufacturing process tends to shift towards green or clean technology where eco-friendly aspect of gas, arc, and laser welding is significant. At extremely high temperature of arc welding process, the hazardous environment is created by formation of fumes, vaporization of elements and condensation of vapours to solid particles. In plasma arc welding (PAW), gas metal arc welding (GMAW) and gas tungsten arc welding (GTAW), the shielding gas act as protective atmosphere rather than the use of flux from electrode coating. It may produce the metallic oxides and metallic particles during the process. The use of flux is essential for shielded metal arc welding (SMAW) and submerged arc welding (SAW) according to principle of the technology. All these processes bring three different aspects from economical point of view. The shielding gas (mostly inert type gas) is expensive than using coating on electrode or flux. Therefore, the economical aspect is significant here. GTAW is usually used for relatively thin material whereas GMAW is used for higher thickness material with a pre-defined groove. SMAW or SAW is normally used for large scale welding process. Secondly, the fumes or localized distribution of shielding gas creates the health hazards. Apart from all these difficulties, the consequence effect are impaired because of the melting of the materials to create permanent coalesces. Third, the degree of automation of this welding process is an important aspect since a semi-automatic system is partly manual. The controlling of so many parameters in arc welding process with a feed-back system is really a challenging task (Rout *et al.*, 2019). Most of the arc welding technology are manually operated or in the mode of semi-automatic. In that respect, the solid-state welding is automated with ease as compared to arc welding processes. Therefore, the melting of material as well as the arc welding technology both are negative factors to compromise with the eco-friendly aspect of the process.

Chang *et al.* (2015) analysed the environmental impacts of the fusion welding processes between manual and automatic GMAW, automatic laser-arc hybrid welding, and manual metal arc welding (MMAW). Out of these processes, the manual operation ensures the excess amount of energy consumption viz. the filler material as well the coating on it due to lack of control on metal transfer. Therefore, MMAW contributes the highest amount of emissions to the environment and consequently the global warming. The secondary impact of the manual process is to bring the risk of health hazard as compared to shop floor automatic process. In that respect, the laser welding is eco-friendlier and easy to automate than arc welding processes due to supply of well controlled and stable laser power, flexibility of power diffraction by pulsation and easily focus on a particular area (Kashaev *et al.*, 2018). Most often, laser welding is assisted with shielding gas and creates less hazardous environment as compared to arc welding processes. The electron beam welding (EBW) operates under vacuum and ensures the highest quality of fusion welded structure since the contamination of the weld pool is the minimum under protected atmosphere (Dinda *et al.*, 2019). Therefore, EBW is eco-friendlier than laser or arc welding processes, but, the cost of the technology is not comparable. The inverter power supplies for semiautomatic welding process create the economic benefit when welding is performed in a protective gas environment (Petrov *et al.*, 2017). It involves the machine installation and training cost along with cost of consumables like electrodes and shielding gas etc. Thus, the use of inverter power supply for the development of advanced welding equipment is technologically and practically justified from the economic point of view. Campbell *et al.* (2012) showed the economic and technological benefit of a sophisticated shielding gas flow controller based on self-regulating device than a conventional flow meter used in GMAW process. There was a cost savings of $\sim 50\%$ in shielding gas by reducing the gas flow rate to 6 L/min without compromising the weld joint quality. This technical upliftment has several lateral advantages. Clean weld is produced at this low gas flow rate which is free from localized current of gas. It enhances the potential savings by drastic reduction in gas flow rate. The electromagnetic gas saving device responds very rapidly which is beneficial to minimize the wastage of gas during short weld length or pulse welding condition. In this stitch welding case, the consumption of shielding gas is reduced by $\sim 20\%$. The impulse pressure generated by the valve further enhances the weld depth of penetration. Tseng (2006) utilized GA based optimization algorithm to achieve the highest quality of weld joint by minimizing the energy consumption in resistance spot welding process. An optimum combination of process parameters i.e., electrode force, weld on time, current and desirable sheet thickness has been established to accomplish the objective. It is thus obvious that by modifying the welding equipment, or by developing the automatic system or by using the optimum range of process parameters, the impact on environment is minimized or efficient utilization of energy is possible. It needs several interactive studies which currently lack in literature to make fusion welding a green technology or sustainable manufacturing process. In that respect, solid-state welding has the potential to be a green manufacturing process because of several technological advantages over conventional fusion welding processes.

The ultrasonic welding is one of the solid state welding processes which are eco-friendlier as compared to fusion welding processes (Ni and Ye, 2018). This process is limited in small scale joining where the thickness is limited to only 1 mm. Magnetic pulse welding is another cleaner technology which uses electromagnetic forces and join at a relatively high welding speed (Kapil and Sharma, 2015). The weld interface is free from melting and does not produce hazardous emissions like fume and spatter. However, the magnetic pulse welding is limited by the geometric shape and size of the workpiece which is mainly controlled by the design of the coil used to produce high density magnetic field. The FSW which is designed primarily for light weight structure can overcome the limited thickness of workpiece to be joined as compared to ultrasonic or magnetic pulse welding. However, hybridization of FSW is further development primarily meant for joining dissimilar materials and high strength or high hardness materials.

FSW as Green Technology

To enhance the fuel economy, the automotive industry focuses on to the manufacturing and processing of lightweight materials like aluminum alloys. However, the welding of aluminum using conventional fusion welding processes encounters serious problems like poor microstructure and porosity in the fusion zone (Praveen and Yarlagaadda, 2005). Therefore, processing of aluminum is often preferred by solid state welding processes. FSW is such process developed primarily for aluminum alloys where two materials are joined by plastic deformation through frictional heat generation by a non-consumable and hard tool. The localized frictional heating drives a non-symmetric mixing of the quasi-viscous material occurs due to difference in relative velocities between advancing and retreating sides (Yaduwanshi *et al.*, 2015a,b). Literature are enriched with numerical simulation and soft computing methods of FSW process to analyses the influence of process parameters on internal variables like strain, strain-rate, and temperature distribution. These parameters along with inherent material properties decides the mechanical properties and microstructural characteristics of the weld joint, and if there is any formation of defect (Okuyucu *et al.*, 2007; Xu *et al.*, 2001; Colegrove and Schercliff, 2004; Nandan *et al.*, 2006; Arora *et al.*, 2009b; Neto and Neta, 2013; Chiumenti *et al.*, 2013; Mehta *et al.*, 2015; Fratini *et al.*, 2009; Boldsai Khan *et al.*, 2011; Alkayem *et al.*, 2017). With the advancement of high performance computational facility, the process model of industrial need are of growing interest either for processing of a new material or to analyse the differential influence of process parameters. Therefore, a reliable modeling and simulation of FSW process demands the validation with experimental result. However, the requirement of the number of experiments is less which minimizes the adverse effect on environment. Also, the economical aspect in conducting the experiments in terms of usage of materials, involvement of cost and time, power or fuel usage and emission to environment are reduced substantially. The green manufacturing pertinent to computational facility and sustainability of electronic items are significant for analysing the

eco-friendliness of computer model for FSW process. The main challenge is the disposal of computer waste like lead and recovery of gold from circuit boards during recycling of computer wastes (Williams, 2004; Kahhat and Williams, 2009; Babbitt *et al.*, 2009; Chu *et al.*, 2009; White *et al.*, 2003; Fukuda *et al.*, 2003). Development of green and biodegradable electronic products is one of the solutions to reduce the environmental impact where organic materials are good candidate to be used in electronics manufacturing (Bar-Cohen and Iyengar, 2003; Irimia-Vladu *et al.*, 2012). Organic paper can be used to produce low voltage circuit and an electronic sensor can be made from biodegradable silk. The flexible conductive polymer (polyaniline and polypyrrole) can be used in biological system that holds other mechanical properties while being nontoxic (Irimia-Vladu *et al.*, 2012).

FSW is environment friendly due to absence of any smoke and fumes which is usually common in conventional fusion welding processes. The frictional heat is responsible for the plastic deformation and mixing of softened material where heat generation is restricted to below melting point temperature. FSW ensures effective utilization of the energy as compared to fusion welding processes and the eco-friendliness is explained from several aspects. There is no use of shielding gas and fumes from coated electrode in FSW. No production of infra-red, ultra-violet ray or x-ray like laser or electron beam welding processes. In general, FSW technology is free from air, water, and soil pollution and therefore, is considered as a green technology. FSW is easily automated as compared to arc welding process where the uncertain factors related to arc stability, arc gap and responsive feedback system play significant role. To alleviate this probabilistic effect, the control system becomes complicated and expensive in arc welding process. Therefore, the possibility of automation provokes FSW as economically sound process as compared to conventional and advanced fusion welding processes.

FSW is significantly less energy intensive than competing technologies, while offers cost savings, and increases in productivity by sophisticated and automated system. The limitation of FSW is the inability to be used on-site and lack of development of this technology for relatively thick-section welding. With different grades of aluminum alloy, FSW is widely used in mainly aerospace, shipbuilding, automotive sector, and power generation sectors. Dawood *et al.* (2014) investigated the environmental impact in a comparative analysis mode between FSW and GMAW in joining of Al alloys. For similar range of weld joint strength, the power consumption has been reduced to one-fourth using FSW technology. Also GMAW creates higher heat affected zone (HAZ) than FSW process. GMAW releases large amount of greenhouse gases (CO - 2.7 ppm and CO₂ - 346 ppm) as opposed to 0.6 ppm and 211.6 ppm, respectively, in case of FSW. The microstructure of weld nugget consists of small grains as compared to solidified fusion zone which helps to predict higher tensile strength for FSW process (Anjaneya and Prasanna, 2013). Kumarana *et al.* (2011) analysed the eco-friendly aspect of friction welding during joining between tube and flat workpiece by comparing with GTAW process. A detail analysis of the material wastage, mass utilization, labor cost, consumable and power utilization were performed. It was concluded that the eco-friendly aspect for GTAW is hindered due to loss of alloying elements, high distortion, requirement of flux, use of filler wire and shielding gas, formation of defects like porosity and crack.

It is thus obvious that FSW has several accredited advantages over fusion welding processes. It has also limitation in several aspects, specifically for joining of high strength material and joining of dissimilar combination. The practical solution of these limitations drives towards the development of hybrid FSW process with optimum utilization of resources as well as to deliver the highest quality product. For example, the welding between steel and aluminum dissimilar combination by conventional FSW process insufficiently plasticized the steel at nearly melting temperature of aluminum. Mixing of these metallic materials may create porosities and other kind of welding defects. Moreover, high welding force and variable stress on the tool due to difference in hardness impairs tool wear and demands proper design of fixture, tool, and backing plate. The common solution of the problem is encountered in two different ways. The first one is to develop FSW tool made from very hard materials like tungsten carbide, silicon nitride, or PCBN with complex geometric shape. The second option is to explore different hybrid process where secondary energy sources are integrated with primary process. However, the objective parameters of hybrid process is to reduce the load on tool, reduction in tool wear i.e., enhanced tool life, alleviating faster weld speed, and minimizing the energy consumption.

Hybridization of FSW

The global warming enforces the development of eco-friendly manufacturing processes that have minimum impact on the environment and energy demand. FSW is one of the finest green manufacturing processes where environment impact is the minimum as compared to fusion welding processes. However, conventional FSW may not be feasible always or may not utilize optimum resources for high strength and high melting point material, and specifically for welding of dissimilar material where a wide difference in physical properties exists. In principle, hybridization of the FSW process holds the advantages of conventional FSW process but enhance the application towards the difficult-to-weld material within a frame of solid-state process. FSW is hybridized by introducing different kinds of secondary heat sources like arc, oxy-fuel, induction coil, and ultrasonic vibration etc. Use of induction coil and ultrasonic assisted FSW does not involve any greenhouse gas and maintain almost similar eco-friendliness like FSW. However, arc-assisted or laser-assisted or oxy-fuel assisted hybrid FSW creates environmental hazard to a lesser extent since the maximum temperature of the system is restricted to below the melting point temperature of the substrate material. The objective of hybridization is to enhance the product quality which is otherwise difficult to achieve using conventional FSW process alone. Hybrid FSW is an intermediate status quo between the limitation of FSW for relatively harder material, less tool wear and enhanced tool life, and conventional fusion welding processes. It is obvious that the product quality is enhanced in hybridization of FSW process by compromising the eco-friendliness with the application of external heat. Frictional heat and tool wear may not appropriate in case of classic FSW process to weld relatively harder material. Hence the efficient utilization of energy is compromised by adding other secondary heat sources. The loss of heat energy by

convection and radiation is high due to arc or oxy-fuel heat source otherwise FSW tool utilize frictional and deformation heat energy with minimum loss. However, HFSW may be more energy efficient than conventional FSW process because of the reduction of tool force with the application of auxiliary heat source.

Literature are rich in the development of HFSW processes mainly categorized as induction, ultrasonic, laser, plasma arc, gas tungsten arc, and oxy-acetylene assisted FSW processes (Sinclair *et al.*, 2010; Álvarez *et al.*, 2014; Palm, 2004; Bang *et al.*, 2010; Yaduwanshi *et al.*, 2018, 2016, 2014; Lotfi and Nourouzi, 2014; Choi *et al.*, 2011; Lai *et al.*, 2014; Shi *et al.*, 2015; Strass *et al.*, 2014a,b; Liu *et al.*, 2015a,b; Liu and Wu, 2013). Friction surfacing assisted HFSW is another variant of hybridization of the process. The secondary heat source plays dual role in hybridization of FSW process. One is the reduction of the flow stress difference and other is the partial heat treatment of the welded joint. HFSW applied for light weight dissimilar combination of materials mainly reduce the self-weight in aerospace and automobile structure. In effect, the light weight reduces the fuel efficiency and hybrid process moderate the environmental pollution. In this aspect, the light weight joint between Al and Mg alloys is mostly used in industry. However, the main obstacle of successful weld joint is the formation of brittle intermetallic layer at the interfaces. The harmful intermetallic phase is more easily controlled in hybridization of the FSW process as compared to conventional arc or laser welding processes. The offset of the secondary heat source towards harder material enhance material flow and the offset of FSW tool towards softer material control the brittle intermetallic components during joining of dissimilar combination of materials. A number of successful HFSW technologies have been developed during last decade having their own limitations in terms of application area, environmental friendliness, efficiency and economical aspect (Padhy *et al.*, 2016; Seif *et al.*, 2018; Bang *et al.*, 2013, 2012; Joo, 2013; Campanelli *et al.*, 2013; Merklein and Giera, 2008; Chang *et al.*, 2011; Ruilin *et al.*, 2014; Conrad, 2000; Pitschman *et al.*, 2010; Luo *et al.*, 2014; Long and Khanna, 2005; Álvarez *et al.*, 2014; Nguyen-Tran *et al.*, 2015; Siddiq and Sayed, 2012; Tarasov *et al.*, 2017; Benfer *et al.*, 2017; Park *et al.*, 2008; Strass *et al.*, 2014a,b).

Seif *et al.* (2018) developed oxy acetylene flame assisted HFSW process for TRIP steel. Although oxy-fuel creates CO and CO₂, the welded joint achieves several technological benefits. The presence of martensite and bainite phases in the welded joint enhances the hardness. Welding of high carbon steel by assisted with gas torch effectively influences on the cooling rate during welding (Choi *et al.*, 2011). Reduced cooling rate decreases the volume fraction of martensitic phase and hence the weld joint strength and elongation are enhanced as compared to conventional FSW process. Lotfi and Nourouzi (2014) investigated the influence of preheating by using a gas heating system on aluminum alloy. It was observed that the formation of defects is reduced noticeably with extra heat supplied by auxiliary gas heating system. The weld joint efficiency enhanced remarkably not exceeding than 83%. However, burning of the fuel to the on-site process development is not a feasible solution for the development of green technology. Moreover, localization of the heat concentration is not up to the mark by a gas heating system since heat energy distributes over a large area to produce relatively wide HAZ. The arc based secondary heat source is better option to create more concentrated heat energy.

HFSW of aluminum alloy and titanium alloy was successfully achieved using GTAW process that preheats the sample towards Ti alloy (Bang *et al.*, 2013). Offsetting heat source towards Ti-side reduces the flow stress difference, and equilibrates the temperature distribution. The significant improvement of ultimate tensile strength and elongation were achieved by HFSW as compared to conventional FSW process. During joining between aluminum alloy and stainless steel, the elongation of the joint increases significantly due to ease of material flow and partial annealing effect when the external heat offsets towards stainless steel (Bang *et al.*, 2012). Joo (2013) applied gas tungsten arc as preheating source on steel plate during joining with magnesium alloy. The tensile strength achieved by the hybrid process was more than that of conventional FSW process which was ~ 91% of the base material. Similarly, the gas tungsten arc was placed an offset distance towards mild steel. It was reported that the tensile strength was enhanced significantly because there was no adverse effect of brittle intermetallic compounds FeAl and FeAl₃.

Plasma arc-based HFSW has been developed to weld between copper and aluminum (Yaduwanshi *et al.*, 2018, 2016, 2014). High intensity plasma arc supply the required heat energy to recover the lost heat due to high thermal conductivity of copper and cylindrical tool offsetting towards aluminum side suppresses the formation of intermetallic components in the weld joint. Fig. 4 depicts the schematic diagram of plasma assisted HFSW process. PAW produces more constricted arc than GTA welding, hence,

Fig. 4 Schematic of plasma assisted friction stir welding process. Yaduwanshi, D., Bag, S., Pal, S., 2016. Numerical modeling and experimental investigation on plasma-assisted hybrid friction stir welding of dissimilar materials. *Materials and Design* 92, 166–183.

suitable for joining high conductive material. The efficiency of plasma arc-based HFSW when joining high conductive material is comparatively low because of high heat energy loss to the backing plate. The laser source creates high power density as compared to arc or oxy-fuel based heat source and confined into a small focused area. However, there may be the chances of melting with laser until it is not controlled in the heating mode only.

The laser is more sophisticated heat source in hybridization of FSW process. The emission of hazardous gases to the environment is limited as compared to arc or oxy-fuel based system. In laser assisted HFSW of aluminum alloy, apart from enhanced micro hardness and elongations, the longitudinal residual stress in the weld zone was reduced. Moreover, pre-treatment by laser significantly reduces the transverse residual stress (Campanelli *et al.*, 2013). Merklein and Giera (2008) investigated the preheating effect on steel by a diode laser spot when joining with aluminum. The placement of laser on steel enhanced the energy absorption (> 55%) and the consequence effect was the reduction of intermetallic compounds. Chang *et al.* (2011) developed laser based HFSW process by introducing the third metal as Ni during welding between Al and Mg. This technique helps to remove brittle intermetallic phases and promotes more amounts of ductile phases at the weld interface. The joint strength improves considerably with hybrid process because of Ni-based intermetallic phases which is less brittle than intermetallic formed by Al-Mg.

One of the anticipated objectives of hybridization of the FSW process is to eliminate the oxide alignments, formation of root defect and lack of proper penetration due to deficiency of proper viscoplastic material flow (Santos *et al.*, 2014a; Ruilin *et al.*, 2014). Heat generation by Joule effect improves the material flow. However, the use of external electrical energy is dissipated into the conventional FSW systems by two different ways. The first one is to create the resistive heating where the tool becomes intricate part of the system and delivers high intensity current to a localized area (Santos *et al.*, 2014b). The secondary is to pass the electric current to an external system or to utilize induction coil aided to the conventional FSW system. Fig. 5 depicts the development of electrical energy assisted hybrid FSW processes. It mainly accounts how the electrical circuit is embedded with the conventional FSW system (Padhy *et al.*, 2015). There are several advantages of using electric current in traditional FSW process. The electric current influences the solid-state transformation by the formation of intermetallic compound, precipitation, and recovery, recrystallization and grain growth (Pitschman *et al.*, 2010). Electricity could affect the material structure other than resistive heating. The deformation behaviour due to application of electric current eliminates the springback effect and reduces tool wear (Pitschman *et al.*, 2010).

Santos *et al.* (2014b) indicated that the resistance heating by a conducting medium through small part of the FSW tool provides good stirring of the material during welding of aluminum alloy. The tool may also equip with several other features like gas shielding, cooling channel, and insulation (Luo *et al.*, 2014). This tool is used in more beneficial way for joining similar and dissimilar materials aided by resistance heating. Even the whole tool of FSW acts as an electrode through which the current flow and this hybrid system has been used to join steel and titanium (Long and Khanna, 2005). This hybrid system helps to reduce the flow stress resistance in through thickness direction because of large area involvement by the FSW tool. However, Joule heating may create electro-plastic effect i.e., soften the material during plastic deformation without substantial increment of temperature. This effect is significant for metals subjected to either high density pulse of extremely short duration or smaller continuous current. However, FSW tool equipped with so many features create the design of the tool more complex and often compromised with tool strength due to resistance heating and electro-plastic effect that leads to considerable tool wear. Liu *et al.* (2015a) developed an electrically assisted FSW system which creates the Joule effect externally where the conductive electrode is attached with the tool. It is advantageous since the tool is not involved in the electrical circuit as well there is no restriction on geometric size to be welded. This hybrid FSW is used to join dissimilar combination of aluminum alloy and TRIP steel. Along with Joule heating, the electro-plastic effect reduces the axial force and confines the crack initiation within the intermetallic layer at the weld interface. The electro-plastic effect becomes more prominent at low rotating speed of tool and at very low tool offset.

Sinclair *et al.* (2010) developed the hybrid FSW system by placing the induction coil under the aluminum sample insulated from the welding machine. The induction heating results in a noteworthy reduction (43%) of the axial force and the flow of the material has been improved over a relatively large area to produce stronger weld joint. Álvarez *et al.* (2014) applied induction heating for welding of commercial cast super duplex stainless steel. With the preheating technique, the welding speed is enhanced to twice when compared with conventional FSW process. The enhanced strength and hardness of the joint is attributed to the refinement of grain size by dynamic recrystallization. The fine-grained banded structure in the stir zone consists of ferrite and austenite. In general, electrically assisted manufacturing processes are aided by the theory of electro-plasticity (Nguyen-Tran *et al.*, 2015). This technique is energy efficient, cleaner with reduced processing time as compared to other auxiliary energy sources. However, the fundamental study on the application of electro-plasticity pertinent to the development of hybrid FSW processes is lacking in esteemed literature. Moreover, the controlling of localized heating by induction coil is more challenging due to placement of coil in appropriate position. It is limited by the geometric shape and size of the workpiece. In mechanically assisted FSW, the ultrasonic energy is more appropriate to affect directly the micro scale behaviour by localization of energy as compared to induction heating.

Ultrasonic impact is normally used in welded structure to relieve the residual stress where a compressive stress is produced on the subsurface layer. With similar principle, high frequency ultrasonic energy decreases the yield strength of the material over a much localized area having similar effect of thermal softening. A rough estimation shows that the ratio of required ultrasonic energy to thermal energy to produce same amount of softening is $\sim 10^7$ (Siddiq and Sayed, 2012). The ultrasonic energy is mainly absorbed in localized dislocation and surface defects of crystal structure whereas the thermal energy spreads almost homogeneously over a large area. Acoustic softening effects are responsible for the reduction of yield strength which depends on the intensity, but independent of frequency. However, the effective transmission of ultrasonic energy in a hybrid FSW system depends

on whether the unit is attached to the tool or to the workpiece (Padhy *et al.*, 2015). Fig. 6 depicts different configuration of ultrasonic assisted hybrid FSW processes (Padhy *et al.*, 2015). Directly transfer of ultrasonic energy to the tool may affect the material properties due to acoustic effects. The positioning of the sonotrode on the workpiece is also an important factor for effective utilization of ultrasonic energy. The inclined sonotrode's axis does not ensure full utilization of energy and only normal component of oscillation transmits to the workpiece. Moreover, there may be loss of energy due to friction and deformation when there is a lack of stiff contact between sonotrode and the workpiece (Padhy *et al.*, 2016). The intense localized deformation and heating is favoured by high-frequency and low amplitude ultrasonic vibrations. Here the heating works in two folds i.e., softening of localized material and reduction in work hardening effect of sonotrode tip. Tarasov *et al.* (2017) followed different approach

where the ultrasonic energy is directly transmitted to the workpiece through backing plate. This technology ensures homogeneous effect of ultrasonic energy throughout the workpiece.

In general, ultrasonic assisted FSW impacts more on microstructural phenomena. It facilitates the intermetallic precipitates, reduces the grain size by recrystallization, and enhances precipitation of coherent metastable phases. This process eliminates the brittle intermetallic Al_3Mg_2 and increases the weld joint strength between Al and Mg (Tarasov *et al.*, 2017; Benfer *et al.*, 2017; Park *et al.*, 2008). Localization of ultrasonic energy also facilitates the strain induced dissolution of coarse Al-Cu-Fe-Mn particles (Siddiq and Sayed, 2012). Liu *et al.* (2015c) showed that ultrasonic energy influences on strain or strain rate induced deformation and material flow behaviour that impact on the metallurgical characterization of the welded joint. Benfer *et al.* (2017) showed that the corrosion properties of welded joint have been improved with the introduction of ultrasonic assisted hybrid FSW process between aluminum and steel. Liu *et al.* (2015b) investigated the ultrasonic assisted FSW on aluminum alloy in butt joint configuration. The mechanical properties like joint strength and micro hardness, and welding speed has been improved. The fracture location has been shifted from nugget zone to HAZ or THAZ. Ruilin *et al.* (2014) indicates that the ultrasonic energy does not increase the temperature much at low welding speed whereas it is significant at higher welding speed. Strass *et al.* (2014a,b) showed that ultrasound smashes the brittle interlayer during welding between aluminum and magnesium and improves the joint strength up to 30% as compared to conventional FSW process. Fusion welding of heat-treatable Al-Cu-Li-Mg-V alloy has the difficulty of producing both voids and hot cracks. Using FSW for this material, the risk of hot cracking aided by high tensile stress in the HAZ is reduced. However, the presence of in-homogeneously distributed residual stress is generally removed by laser and shot peening. Using ultrasonic assisted FSW improves the weld joint strength for such a complex alloy (Tarasov *et al.*, 2017). The process of friction surfacing assisted hybrid FSW technology has been developed mainly to avoid the pin abrasion for joining of

dissimilar Ti/Al joints (Huang *et al.*, 2017). The FSW tool is designed with enlarged head and concave end-face to facilitate the widening of lap width. It promotes the material flow mixing over a large area. The hybridization of FSW by integrating another solid state based processing technology open some new window for improving the joint strength as well as promotes greener or cleaner technology.

Conclusions and Future Scope

Literature indicates that the hybridization of FSW process has been developed at aiming some practical problems faced by either FSW or fusion welding processes. However, the development of hybrid FSW processes has the potential to explore as a futuristic eco-friendly process. The current status indicates that the economical and sustainability aspect is less focused for hybrid FSW process since very few literatures has come up to this particular subject. However, there is potentiality to improve this process in the forefront of clean technology or green technology. The present article describes the technological advancement of hybrid FSW processes first and then the economic benefit arises due to hybridization of FSW process. Although many hybridization of FSW process have been developed, all processes are not in the forefront of green technology. The developments occur as a cause of current industrial needs rather to the consequence effect on the environment. The developments of hot gas stream, gas/arc, laser assisted FSW is to-some-extent crude process where the effects on environment is not negligible and may not economic always since there may be considerable loss of energy from the secondary heat sources. Electrically assisted and ultrasound assisted FSW fulfilled certain industrial need and free from any kind of direct impact on environment. However, all these developments are not commercially successful for welding on a large scale due to capital and maintenance costs as well as difficulty in up scaling of the process (Potluri *et al.*, 2013). In that sense, the electrically assisted FSW has less geometric constraint to use in a large scale welding process. It is more economic process when the direct current passes through the workpiece. There is considerably decrease in feed force (average $\sim 59\%$) and the initial torque required by the tool as compared to conventional FSW process.

The auxiliary energy assisted FSW mainly modify the deformation behaviour of materials measured by internal parameters like strain, strain rate, and temperature. The flow stress behaviour, macro, and micro structural characteristics mainly affect the weld joint hardness, strength properties, and elongation. The fundamental work on the interaction of electric current with the engineering materials for the development of hybrid FSW process is lacking in the esteemed literature. These studies are expected to optimize the process time and manufacturing cost in hybridization of FSW process. The development of hybrid FSW considering electro-plasticity effect has still not been fully developed and there is a possibility for further development using fundamental theory. A sustainable model seems lacking in HFSW processes. Although very limited literature is found corresponding to the eco-friendly aspect of HFSW processes, there is a huge scope to establish HFSW as a promising technology that balance between technological challenges and environmental impact.

Eco Friendly Flocculants: Synthesis, Characterization and Applications

GP Karmakar, Indian Institute of Technology, Kharagpur, India

Introduction

The treatment of waste water and industrial effluent may be carried out using either with inorganic or organic coagulants and flocculants. For coagulation and flocculation, although the basic function remains the same, subtle distinction is made between these two terms. The coagulation means the destabilization of a stabilized system (e.g., colloidal system) but flocculation means the floc formation of the destabilized colloidal system, where the addition of flocculant to the destabilized colloidal system results in flocculation. The flocculants may be either inorganic or organic type. Among the inorganic flocculants, the multivalent metallic compounds like aluminium and iron salts are generally used. The organic polymeric flocculants are preferred due their ease in handling, low dosage requirements, less sensitivity to system pH, existence of large cohesive forces between the flocs and the ease in synthesizing the flocculants. Polysaccharides such as starch, amylose, amylopectin, guar gum, xanthan gum and carboxymethyl cellulose have been used for as long as natural flocculants. However, they are less effective flocculating agents when compared with synthetic flocculants. Polyacrylamides have also been used for long some time as synthetic flocculants. Although their flocculation efficiencies are higher than the natural flocculants, these synthetic polyacrylamide flocculants are easily amenable to shear degradation even at low ppm concentrations. Whereas, polysaccharides are fairly shear stable but are not very efficient flocculants. Their aqueous solutions are also subjected to rapid biodegradation. It has been observed that by grafting polyacrylamide branches on the backbone of polysaccharide molecule, efficient flocculants with biodegradable resistant as well as shear resistant properties could be developed.

Synthesis of Graft Copolymers

Materials and Methods

The following materials have been used for the synthesis of the graft copolymerization experiments: (i) Soluble potato starch (GR grade) Loba Chemie, India; (ii) amylose from corn (Practical Grade), Sigma Chemicals Co., USA; (iii) acrylamide (GR grade), Merck-Schuchardt, Germany; (iv) ceric ammonium nitrate (Reagent grade), Loba Chemie, India; (v) nitric acid (Analar grade), BDH, India; (vi) acetone (Analar grade), BDH, India; (vii) Magnafloc-1011, Allied Colloids, UK.

Synthesis of Graft Copolymers

The starch solution was prepared in deionised double distilled water at 80°C and then cooled to room temperature. Subsequently, the grafting reactions were performed using ceric ammonium ion initiated redox polymerization technique and scaled up as mentioned elsewhere (Ungeheuer *et al.*, 1989). For amylose grafted copolymers, only the laboratory scale experiments were carried out for 3, 5 and 7 h using the same procedure as above.

The details of the graft copolymers are given in Table 1.

For each set of reactions 1 g of starch/amylose was taken. The acrylamide and catalyst concentrations in the reaction mixture were 0.14 and 0.03×10^3 moles respectively.

SAM-L-I: Starch grafted polyacrylamide (Laboratory-I)

SAM-L-II: Starch grafted polyacrylamide (Scale up-II)

AML-AM-L-3: Amylose grafted polyacrylamide (Laboratory, 3 h.)

AML-AM-L-5: Amylose grafted polyacrylamide (Laboratory, 5 h.)

AML-AM-L-7: Amylose grafted polyacrylamide (Laboratory, 7 h.)

Table 1 Details of the graft copolymers

Graft Copolymers	Yield %	$[\eta]$ at $30 \pm 0.1^\circ\text{C}$	Number average mol.wt. $M_n \times 10^6$	Weight average mol.wt. $M_w \times 10^6$
SAM-L-I	85.70	660	1.10	1.88
SAM-L-II	89.71	820	1.52	2.46
AML-AM-L-3	58.93	700	1.20	2.02
AML-AM-L-5	75.20	720	1.25	2.09
AML-AM-L-7	74.45	710	1.22	2.06

Characterization of the Synthesised Flocculants

The intrinsic viscosities $[\eta]$ at $30 \pm 0.1^\circ\text{C}$ of the graft copolymers have been evaluated as per standard procedures and are given in **Table 1**. From the intrinsic viscosity values, the approximate molecular weights of the grafted products have been calculated using the following equations (Mendelson, 1969):

$$[\eta] = 6.8 \times 10^{-4} (\text{Mn}^-)^{0.66} \quad (1)$$

$$[\eta] = 6.31 \times 10^{-5} (\text{Mn}^-)^{0.80} \quad (2)$$

The above relationships have been used for evaluating the molecular weight of the graft copolymers of polyacrylamide (Erciyes *et al.*, 1992). The results obtained are given in **Table 1**.

Elemental Analysis

The results obtained from the elemental analysis have been given in **Table 2**.

It has been found that out of the five synthesised copolymers, SAM-S-II and AML-AM-I-5 are having the higher percentage of elemental nitrogen in their molecules. The increased percentage in nitrogen content indicates higher grafting efficiency and higher yield of the synthesised graft copolymer. McCormick and Lin (1981) also found the similar results while synthesizing dextran-grafted acrylonitriles by Ce(IV)/HNO₃ induced initiation method. They observed that when the nitrogen percentages were high in the grafted products, the intrinsic viscosities as well as the molecular weights were also high.

Scanning Electron Microscopy

Scanning electron micrographs for the monomers and the graft copolymers are shown in **Figs. 1–8**.

It is clearly found that in the graft copolymers of starch, granular structure of starch and the polycrystalline structure of acrylamide are absent in both laboratory scale and scale up products. For both starch and amylase grafted products, substantial amount of grafting is noticed for all the grafted products. The above phenomenon supports the grafting of acrylamide onto starch/ amylase. Similar results were also obtained by Yao and Tang (1992) during characterization of starch-g-poly (acrylamide-co-sodium allylsulfonate) synthesised by Ce (IV) method.

Thermal Analysis

To find the effect of grafting on thermal stability and various transition in polymers, thermo gravimetric analysis (TGA) and differential scanning calorimetry (DSC) were carried out for starch, amylose and their grafted products.

During TGA, the change in weight of a sample is measured as a function of temperature while the sample is subjected to a controlled heating programme. On the other hand, DSC is the process whereby the energy change is measured as a function of temperature during the controlled heating programme of the sample. Thus, TGA measures the loss in weight and DSC gives the information about absorption or evolution of heat during the reaction.

Thermal analyses were carried out using STA 625 STANTON REDCROFT thermal analyzer. The sample was varied from 4.5 to 5.5 mg. The sample was heated at the rate of 10°C per minute under nitrogen using Al₂O₃ as reference from 0° to 600°C . Initial and final decomposition temperatures (IDT and FDT) were recorded along with various stages of decomposition. The results are presented in **Table 3**. The loss of weight in the region up to 100°C depicts minor endothermic reactions due to the loss of moisture contents (5%–11%).

For starch, the gelation temperature is found to be 65°C followed by strong endotherms at around 280°C . For SAM-I-1, the gelation temperature is noticed at 68°C and the initial decomposition starts at 230°C and final decomposition takes place at around 421°C . In case of SAM-S-II initial melting or fusion takes place 228°C and final decomposition takes place at 442°C .

For amylose, after a gelation temperature of 66°C , the initial decomposition takes place at 264°C and the final decomposition temperature at 360°C . For amylose grafted products, the initial decomposition temperatures are found to be 265°C for AML-AM-I-3, 320°C for AML-I-5 and AML-I-7 products. The final decomposition temperatures for AML-AM-I-3, and AML-I-5 and AML-I-7 were found to be 410°C , 422°C and 425°C respectively.

Table 2 Results of Elemental Analysis

Materials	N(wt%)	C(wt%)	H(wt%)
SAM-I-I	14.5961	42.5644	6.9940

It has been observed that the initial decomposition temperature for amylose and their graft copolymers are higher than that of starch and starch graft copolymers. Severe restrictions of amylose chain motion are believed to involve thermally stable (at temperatures $< 100^{\circ}\text{C}$) junction zones with chain segments of degree of polymerization ~ 50 , which support the thermal stabilities of amylose and its graft copolymers at higher temperatures.

Investigation of the Flocculation Efficiency of the Graft Copolymers

To investigate the flocculation efficiency, screening tests were carried out with bentonite clay-water system. Detailed investigations were carried out to determine the efficiency of starch-g-polyacrylamide and amylase-g-polyacrylamide in comparison with commercial flocculating agents for industrial effluents and hematite slimes.

Fig. 7 SEM of AML-AM-L-5.

Fig. 8 SEM of AML-AM-L-7.

A laboratory jar test apparatus known as flocculator (MB-Flocculator; M. B. Instruments, Mumbai, India) was used for flocculation measurements. It consists of six stirrer blades connected to a motor, the speed of which can be controlled automatically with the help of a selector switch fitted on the panel board. The following sequence of operations was followed:

- (1) Four to six numbers of effluent samples were taken in beakers according to the respective plan of studies. Care was taken so that the stirrer blades were submerged in the effluents up to sufficient depth for proper stirring/mixing.
- (2) Rapid mixing at 60/75 rpm for 2 min was done immediately after the addition of the flocculant for complete mixing of the flocculant with the particles in the effluent.
- (3) Slow mixing at 20/25 rpm for 10–15 min was given for the floc formation at a low stirrer speed of the flocculator.
- (4) Settling time of 25–30 min was provided for the flocs to consolidate at the bottom of the beaker. This was done after removing the stirring shaft and taking out the beakers from the flocculator base plate. As the flocculation and the consolidation of the flocs were over, the supernatant liquid was used for turbidity measurements using a turbidity meter. For all systems, the flocculation efficiency and turbidity values were determined as per standard methods used by American Public Health Association (APHA, 1998).

Turbidity Measurements

A Systronics Digital Nephelo-Turbidity Meter 132 (Systronics, Ahmadabad, India) was used for the measurements of the turbidity of the supernatant liquids in standard Nephelometric Turbidity Units (NTU). The principle operation of this instrument is based on the Tyndall effect. Standard turbidity suspension was prepared prior to the standardization of the turbidity meter. The turbidity measurements were performed as follows.

The instrument was switched on and allowed for 10–15 min to warm up. The selector switch was placed in the appropriate range of NTU values (0–1, 10, 100 and 500 NTU). The ‘standardize’ control was set at maximum. The test tube (provided with the

instrument) was filled with deionised double distilled water and was inserted into the cell holder. It was then covered with the light shield. The 'Set Zero' control was adjusted for the zero setting of the Digital Panel Meter (DPM) to read zero. The test tube was then removed and was replaced with another test tube containing standard solution. The test tube was aligned as per markings on cell holder. 'Standardize Control' was then adjusted such that the DPM indicates '100' in accordance with the standard solution of the appropriate range. The instrument was then ready for test samples. The test tube containing unknown sample was inserted in the cell holder and the reading on DPM was noted in NTU. For 0–500 NTU range, a cell riser was inserted prior to standardization and standardization was done in such a way that 500NTU solution reads '50' on the meter.

Flocculation of Clay Materials

Starch, amylase and their graft copolymers, and bentonite clay were used. To find out the flocculation efficiency of the graft copolymers, screening tests with bentonite clay-water solutions were carried out. For starch and amylase, 100 ppm concentration and for the starch/amylase graft copolymers, 10 ppm concentrations were used for the screening tests. During screening tests, only flocculant was used for floc formation and was observed visually. In each of the six beakers of 1 litre capacity, 8 gms of clay samples were dispersed in 800 ml of distilled water. Starch, amylase and their graft copolymers are used as flocculants. With care, the stirring shafts of the flocculator were lifted and beakers were placed beneath the respective stirrers. Then the stirring shafts were lowered and required amount of flocculant solution of specified concentration was added to respective beakers. With speed control switch, the stirrer speed was selected at 50 rpm for 2 min. The stirring was continued for another 15 min at 20 rpm and then flocs were allowed to settle for 25 min. It was observed that starch and amylose grafted polyacrylamides were more efficient than either starch or amylose. Later on, the flocculating efficiency of the starch-grafted and amylose-grafted was tested with hematite slimes and industrial effluents.

Flocculation Studies With Hematite and Industrial Effluents

In this study the flocculation experiments were carried out for hematite slimes of size 80%, – 9.66 micron. Starch, amylose and their graft copolymers along with a commercial flocculant Magnafloc-1011 were used as flocculants. The effect of varying pH, solid concentration of pulp and flocculant dose was studied.

The flocculation studies on the hematite slime sample were carried out using settling tests and filtration tests. The settling tests following the flocculation of the particles were carried out in a 100 ml graduated cylinder by recording the movement of the suspension-liquid interface as a function of time. The contents of the cylinder were inverted 20 times before being allowed to settle for observation of flocculation and sedimentation. The filtration subsequent to flocculation was studied by observing the amount of filtrate passing through the membrane as a function of time (Karmakar, 1994).

The above standard tests were performed while carrying out the flocculation studies using the above synthesised flocculants. The results of the above tests are given in Figs. 9 and 10.

Standard jar test methods (Karmakar, 1994; Gregory and Guibai, 1991) were followed to study the flocculation efficiency of AML-AM-L-5 (initial rate of mixing was 75 rpm) using a flocculator as mentioned above. Magnafloc-1011 was used as a flocculant for comparison. The supernatant turbidity values in Nephelometric turbidity units (NTU) were recorded as a function of time after a period of mixing and settling. The results are given in Fig. 11.

Fig. 9 shows the height of interface against time at normal pH(6.4) and at pH 5.0 for 10% pulp density of hematite fines, as described earlier, using AML-AM-L-5 along with amylose and Magnafloc-1011. A flocculant dose of 30 ppm was selected for comparison because settling rate is largely effective in this range (Karmakar and Singh, 1998). When the flocculation was carried out at pH10, no flocculation was observed using AML-AM-L-5 (Karmakar, 1994). Since Magnafloc-1101 is a linear chain high molecular weight polyacrylamide, a greater number of acrylamide groups are available in Magnafloc-1011 for flocculation.

Fig. 10 shows the variation of total volume of filtrate with time for various flocculants at normal pH (6.4), pH 5.0 and pH 10.0. The effectiveness of AML-AM-L-5 is compared with amylose and Magnafloc-1011. It is clearly indicated that the performance of

Fig. 9 Variation of the height of interface with time for various flocculants at 10% pulp density.

Fig. 10 Variation of total volume of filtrate for various flocculants at 10% pulp density.

AML-AM-L-5 is better than that of amylose. However, the performance is not at par with that of Magnafloc-1011 at normal pH (6.4) and at pH 5.0. It is also observed that at pH 10.0, AML-AM-L-5 is not a very effective flocculant for the above system (Karmakar, 1994).

Effect of Shear Rate

The initial turbidity values of the slimes without addition of any flocculant at pH 6.4, pH 5.0 and pH 10.0 were found to be 64 NTU, 52 NTU and 512 NTU respectively (Fig. 11). However, after the initial mixing with a specified amount of AML-AM-L-5 at 75

Fig. 11 Variation of the supernatant turbidity with time for various flocculants at 10% pulp density.

rev min⁻¹ during the flocculation by standard jar test method and then settling, the turbidity values reached the lowest points for all pH values while using AML-AM-L-5 as flocculant. This is due to the effect of the shear degradation resistance of the amylose-grafted copolymer. Magnafloc-1011, being a linear chain polyacrylamide, is not so effective at high shear rates. In the acidic pH range the turbidity becomes the lowest.

In grafted amylose, the approachability of polyacrylamide branches to contaminants increases, making it an effective flocculant (Singh, 1995). It appears that grafted amylose is more shear stable than Magnafloc-1011 due to the multiplicity of polyacrylamide branches on it. The pH has a significant effect on the flocculation efficiency. The settling rates fall substantially in the alkaline range due to a shift from the point of zero charge (6.2) of the hematite fines, and possibly due to adverse coiling of macromolecular chains.

Flocculation Studies With Paper Mill Effluents

Effluent samples were collected from Emami Paper Mills, Balasore, India. The initial pH of the effluent was 5.8 and the turbidity value was above 500 NTU. While treating the effluent, it was observed that it was very difficult to treat this effluent with either alum or polymer alone. Only a combination of coagulation and flocculation can effectively flocculate the diluted effluent. The concentrated effluent solutions (dilution less than 10 times) could not be treated effectively. This is due to the fact that the paper mill effluents mainly contain lignosulfonates, lignin, oligo- and polysaccharides and other high molecular weight colour forming compounds. Even after dilution of 10 times with water, it was very difficult to flocculate the particles with polymeric flocculants alone. The coagulation of the colloidal system was necessary with the metallic coagulants like alum or ferric chloride prior to flocculation. The solubles are generally anionic in character and can be expected to react with added coagulants to generate new colloidal components in the system, as well as to reduce the dose of coagulant/flocculant (Donnan *et al.*, 1981). Again, at high dilution, the initial turbidity is increased due to the presence of the solubles. For the clarification of such system of fines along with the solubles both coagulation and flocculation are needed.

The effluent after collection was diluted up to 20, 40 and 50 times. Afterwards, it was coagulated with three different coagulants, viz., $\text{Al}_2(\text{SO}_4)_3 \cdot 0.14 \text{ H}_2\text{O}$, $\text{Al K}(\text{SO}_4) \cdot 12\text{H}_2\text{O}$ and FeCl_3 . SAM-S-II and Magnafloc-1011 were used as flocculants. Standard jar test method was followed for flocculation and the supernatant turbidity values in NTU were measured after specified period after flocculation.

Fig. 12 shows the coagulation-flocculation after 10 times dilution of the effluent. The diluted effluent was first coagulated with $\text{Al}_2(\text{SO}_4)_3 \cdot 0.14 \text{ H}_2\text{O}$ by fast mixing at 50 rpm for 2 min. Subsequently it was subjected to slow mixing for 10 minutes and settling for 30 minutes. The 10 ppm concentration of polymer SAM-S-II was fixed while varying the alum concentrations from 50 to 2250

Fig. 12 Variation of supernatant turbidity with changing alum doses for paper mill effluents.

ppm. It is observed that as the alum concentration increases, the turbidity of the supernatant liquid increases from 27.5 NTU at 50 ppm to nearly 50 NTU at 1250 ppm of alum concentration. When the alum concentration is increased further, bigger size of floc formation is observed at 1500 ppm onwards and the turbidity of the supernatant liquid is gradually lowered to 7.8 NTU at 2250 ppm of alum concentration.

Next, the effluent sample was further diluted to 20 times with water and then was coagulated and flocculated by addition of the same alum and polymer respectively, by standard jar test method. The variation of the supernatant turbidity for various coagulants and flocculants is plotted in Fig. 13. It is observed that after an initial destabilization with 50 ppm concentration of alum, the increase in alum concentration causes restabilization of the fines and the maximum supernatant turbidity of 70 NTU is obtained with 350 ppm concentration of alum. Thereafter, suddenly the supernatant turbidity falls with the addition of more alum and reaches 5.7 NTU at 1000 ppm concentration of alum. It clearly indicates that the dilution of the effluent helps the coagulation of the colloidal system by generating new colloidal systems. Although the polymer concentration of 10 ppm remains constant for both 10 times and 20 times dilution, it can be seen that total quantity of required coagulant for diluted systems is less than the concentrated system alone (at 10 times dilution, 2250 ppm can lower the turbidity to 7.8 NTU and at 20 times dilution, $1000 \times 2 = 2000$ ppm reduces the turbidity to 5.7 NTU).

Similar trend is also observed for more diluted effluents (40 times and 50 times) and the results are depicted in the same Fig. 13.

The effect of various coagulants was also studied in 20 times diluted effluent. The flocculation efficiency of the SAM-S-II after coagulation is shown in Figs. 13 and 14. It can be seen that for this particular effluent, $\text{AlK}(\text{SO}_4)_3 \cdot 12\text{H}_2\text{O}$ is better coagulant than $\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$ and FeCl_3 is the best among these three coagulants.

When FeCl_3 was used keeping fixed dose of 5 ppm SAM-S-II, the turbidity value of the 20 times diluted effluent was lowered to 9.7 NTU with addition of 50 ppm of FeCl_3 . This was further lowered to 0.5 NTU at 600 ppm of FeCl_3 . When compared with Magnafloc-1011, it is observed that, at the lower coagulant dose range (50–70 ppm), the ability to flocculate the coagulated particles by Magnafloc-1011 is better than SAM-S-II. However, beyond 350 ppm dose, increase in coagulant concentration results in sudden fall in the supernatant turbidity to 0.5 NTU by SAM-S-II at 600 ppm (5.8 NTU by Magnafloc-1011) indicating almost total flocculation of the coagulated particles (Fig. 15). Thus when the complex paper industry effluent is diluted and coagulated with ferric chloride and flocculated with the starch-g-copolymer, the supernatant turbidity can be lowered to an acceptable value of 0.5 NTU.

The major control being the electrostatic or charge neutralization, the coagulation must be carried out prior to flocculation by bridging the flocculated particles in the paper industry effluents. Ferric chloride is better coagulant than the alums. This is due to the complicated hydrolysis reactions of aluminium salt solutions which is responsible for the narrower pH range often evident for optimum destabilization when compared with iron salt solution. With iron salts, adsorption follows a Langmuir adsorption isotherm, whereas, with aluminium, adsorption often follows a Freundlich isotherm. This is a further indication of complicated hydrolysis products formed by aluminium salts (Bratby, 1990).

The initial pH of the effluent was 6.9 and after dilution also, the pH remained almost constant. When alum was added, the pH was becoming slowly acidic; but treating with only polymer, no change in pH of the system was observed. This is due to the increase in Al^{+++} ions in the system during the addition of the alum. The same trend of decrease in pH in the system was observed with FeCl_3 treatment due to the increase in Fe^{+++} ions in the system.

While treating the paper mill effluents it is observed that neither a coagulant nor a flocculant can completely flocculate such complex systems. After destabilizing such effluent system with a suitable coagulant, starch-g-copolymer can be used as a flocculant aid for the complete flocculation of the contaminants present in the system. After diluting the effluent, it is possible to clarify the supernatant liquid turbidity below 5 NTU by the combined use of coagulant and SAM-S-II (Karmakar and Singh, 1996).

Besides the above, an account of more detailed studies on polysaccharide based grafted copolymers and their flocculation characteristics have been reported elsewhere by the author and his co-workers (Singh *et al.*, 2000; Karmakar, 2017).

Conclusions

Starch-g-Polyacrylamides are found to be very efficient flocculants for industrial use. The synthesis of these graft copolymers are simple and can be easily manufactured in a large scale. However, real comparison with other commercially available flocculants can be made only when the molecular weights, length of the molecules and number of polyacrylamide chains could be determined by chemical and advanced analytical techniques. The use of the above flocculants also depends on the nature of the effluent to be flocculated. So, the chemical analysis of the effluents is also essential before taking up any industrial project for flocculation.

Amylose, another polysaccharide can be modified by grafting acrylamide monomer onto its backbone to produce a better flocculant using a simple polymerization technique. The amylose-grafted polyacrylamides in small doses have better effectiveness than the commercial flocculant Magnafloc-1011 at high shear rates for a wide range of pH range.

It has also been observed that neither a coagulant nor a flocculant can completely flocculate complex systems. A suitable coagulant may be used to coagulate first and then grafted copolymers can be used for the complete flocculation of such systems.

Electrochemical Energy Storage Using Batteries, Superconductors and Hybrid Technologies

Kamaljit S Boparai, Maharaja Ranjit Singh Punjab Technical University, Bathinda, India
Rupinder Singh, Guru Nanak Dev Engineering College, Ludhiana, India

Introduction

The indispensable requirement of high potential electrochemical energy storage devices (ECESDs) such as batteries, superconductors and hybrid technologies have remarkably increased day by day. It is also critical for highlighting energy crises and environmental issues (Chen *et al.*, 2017). Moreover the performance of these devices also improved dramatically with the advent of advanced materials (Lv *et al.*, 2016). Presently, ECESDs have great demand in electric vehicles and renewable power houses in homes and industries. Despite significant improvement in terms of power density and life span, still it needs improvement for better efficiency. In order to cater for the demand of high performance ECESDs, the efforts were made by many researchers for the development of high performance electrode materials. The three-dimensional (3D) carbon nano-materials due to their distinguished structural patterns of interlinked architecture have various applications for supercapacitors and next generation batteries (Chen *et al.*, 2017). Further they have excellent flexibility, more specific surface areas, tunable interfacial chemical properties and good electrical conductivities, which support executable platforms for the expedition of lithium-sulfur batteries, lithium-ion batteries, lithium-air batteries and super capacitors (Kong *et al.*, 2018).

The above mentioned ECESDs consist of basically four components (electrodes, electrolyte, current collectors, and separators) and 3D printing emerges as a well-timed, flexible tool, presently available with various printing technologies (Tian *et al.*, 2017). Many researchers (Zhang *et al.*, 2017; Ambrosi and Pumera, 2016) reviewed the use of 3D printing technologies for the prosperous of ECESDs. These techniques gains popularity due to its great flexibility in geometrical designs (interfaced with computed aided design and manufacturing) compared to subtractive manufacturing methods (Wu *et al.*, 2015). Moreover, the use of thermal-responsive/ conductive polymers as filament materials in fused deposition modeling (one of the low cost 3D printing techniques) is a step in next-generation smart ECESDs. Foster *et al.* (2017) also demonstrated the use of 3D graphene-based conductive PLA filament for making 3D prints of useful electrochemical parts with bespoke and conceptual designs. Carbon materials have good chemical certainty and versatile nano-structure, can be used in feedstock filament for 3D printing. Moreover, the shape and dimensions of an electrodes (anode/cathode) printed with 3D-printing technology can be precisely controlled besides tailoring the composition (Fu *et al.*, 2017).

Lead Acid Battery

Lead acid batteries are notably used as a storage batteries or secondary batteries, commonly for general application. The materials used for these storage cells are lead peroxide (PbO_2), sponge lead (Pb) and dilute sulphuric acid (H_2SO_4). The positive plate of lead acid battery is made of PbO_2 (dark brown brittle hard substance). The negative plate of lead acid battery is made up of pure lead which is in soft sponge condition. The dilute H_2SO_4 and water have a ratio of 1:3. The PbO_2 plate and sponge lead plate are dipped in a dilute sulphuric acid. A load is externally connected between these two plates. In dilute H_2SO_4 acid, the molecules of acid, split into positive hydrogen ions (H^+) and negative sulphate ions (SO_4^-). The H^+ ions on reaching at PbO_2 plate, receive electron from it and become hydrogen atom (H) which further attack PbO_2 and form lead oxide (PbO) and water (H_2O). Newly formed PbO reacts again with H_2SO_4 and forms lead sulphate (PbSO_4) and H_2O . The SO_4^- ions are moving freely in the solution and some of them reached to pure Pb plate where they give there extra electrons and become radical sulphate (SO_4). Apparently, radical sulphate cannot exit alone, so it attacks pure Pb and become PbSO_4 .

During this process, positive hydrogen ion take electron from lead peroxide plate and negative sulphate ions loose electrons to lead plate, it causes an inequality of electrons between the plates. Hence, the current starts flowing through the external load between these two plates in order to balancing this inequality of electrons. This process is called discharging of battery. As the load is replaced by DC source by connecting lead sulphate covered lead peroxide plate with positive terminal and lead peroxide covered lead plate with negative terminal. During discharging, the density of sulphuric acid falls but there still there is some sulphuric acid exists in the solution. The part sulphuric acid also remains as positive hydrogen ions and negative sulphate ions in the solution. Hydrogen ions being positively charged, moved to the electrode connected with the negative terminal of the DC source. Here each hydrogen ion takes one electron and become hydrogen atom. These newly formed hydrogen atoms, further attack lead sulphate and form lead and sulphuric acid.

The negative sulphate ions proceeds toward the electrode connected with the positive terminal of DC source and loses their extra electrons and become radical sulphate. This radical sulphate reacts with the lead sulphate of anode and form lead peroxide and sulphuric acid. Hence by charging, the lead acid storage battery cells becomes ready for delivering energy to load (discharging).

Nickel Cadmium Battery

In this cell, the anode and cathode are made up of cadmium and metal grid (containing nickel oxide) respectively. In this case, the electrolyte is potassium hydroxide (KOH) solution. The cell has a capacity to generate a voltage of about 1.4 V. No gaseous product produced during the discharge of battery and the solid product formed during the process, adhere to the electrodes which therefore are reconverted by the charging process. These cells are extensively used in electronic watches and calculators.

Nickel Metal Hydrate Battery

The anode in this battery is metal hydride and cathode is nickel oxy hydroxide NiO (OH)_2 . The electrolyte is potassium hydroxide (KOH) solution. Both anode and cathode is made up of nickel alloys and separated by an insulator. Metal hydride is made up of alloys of either zinc, vanadium, titanium, chromium etc. the entire battery is kept in a glass or steel container. Before lithium ion battery is commonly used in laptops and electric vehicles.

Lithium Ion Battery

Lithium ion battery is the indispensable power source of modern electric vehicles. It is rechargeable and have high energy density than other commercially available batteries. Due to its light weight it also used in smart phones, laptops etc. Each battery consists of number of batteries generally called cells. The electric current reaches the cells via conductive surfaces. For these batteries, aluminium and copper are the mostly used conductive surfaces. Like other batteries it also have positive and negative electrodes namely cathode (+) and anode (-). The cathode which is a positive electrode consists of very pure lithium oxide (LiMO_2 ; $\text{M} = \text{Co, Ni}$). More the uniformity in its chemical composition, better is its performance and battery life. The negative electrode (anode) is placed on the other side, is made up of graphite (a form of carbon layer structure). Graphite has been commonly used as the anode material for commercial Lithium ion battery due to its low cost, natural abundance, high coulombic efficiency and flat potential profile during charging and discharging process. A part of above, Lithium alloys are also promising anode materials due to their higher Li storage capacity, which provides higher energy density than commercial Li-intercalated carbons (Guo *et al.*, 2008).

Both anode and cathode have high capability rate but the cycle life of such cells are often limited by the cathode. The unexpected low cathode power competency may be due to either its high electrical resistance or slow transport of Li^+ ion within the solid phase (Gu *et al.*, 2013). A part of above, the metal dissolution from the cathode is also strongly accelerated at elevated temperatures. The battery is built up with a transport medium (the electrolyte) so that the lithium ion carrying charge can move freely. This electrolyte must be extremely pure. To prevent short circuit, there is a layer placed in between two electrodes called separator. The separator is actually permeable to the tiny lithium ions. The experts called this property as a micro-porosity. During charging process, the positive charge lithium ions passed from the cathode through the separator into the layered graphite anode structure where they are stored. On the other hand when battery discharges, the energy is removed from the cell. The lithium ions travels back to cathode via electrolyte through the separator. The motor converts the electric energy into mechanical energy makes the vehicle to run. It is not a one way energy conversion process, the reverse is also possible, electrical energy is also converted into chemical potential and same can be stored in a system. Fig. 1 illustrates the schematic of lithium ions battery.

The availability of energy and its battery life is closely related to the quality of material used. In other words higher the quality of pure materials along with the customized formulation leads to the better performance and longer battery life.

As already mentioned this battery have high energy density which means that it can store larger energy per unit volume or per unit mass as compare to the other batteries (it is almost two times the nickel cadmium batteries. It can be rechargeable until its

Fig. 1 Schematic of lithium ion battery. Reproduced from Guo, Y.G., Hu, J.S., Wan, L.J., 2008. Nanostructured materials for electrochemical energy conversion and storage devices. *Advanced Materials* 20 (15), 2878–87.

battery life is over. It also have no memory effect which means that there is no need to discharge them completely before recharging. It can hold its charge for a certain time (5% energy loss per month)). Even a high energy density battery, it has certain disadvantages. It has a limited life (2–3 years from the date of manufacturing) and very much sensitive to high temperature. If the separator get damaged, it can be burst in to flames.

Future Energy Storage Devices

Super Capacitors

A super capacitor, also known as an ultra-capacitor, is an energy storage device, having much larger capacity than conventional physical capacitors (Liu *et al.*, 2010). Super capacitors are capable of delivering the power at much higher rates than batteries and have been recently used by number of automobile companies (Toyota, Tesla) in energy recovery systems. Super capacitors looks similar to the batteries with low energy density (10–100 times less than Lithium ion battery), high power density (10–200 time more power than Lithium ion battery) and exceptional cycle life (typically 1 million charge and discharge cycles). The longer life of super capacitors is due to the physical movement of ions instead of chemical reactions as the ordinary battery goes. Generally, according to the materials and electro-chemical charging/discharging mechanism, it can be classified as electric double layer capacitors (EDLC) using ion adsorption and pseudo-capacitors having fast surface redox reactions (Cakici *et al.*, 2017) (Fig. 2).

Super capacitors overcomes the limitations of batteries or provides better solution than batteries. Super capacitors are bigger capacitors were invented in the same time of batteries, about 150 years ago. Super capacitors are inherently better storage devices than chemical batteries. They are more efficient, last longer, have resilience to temperature, do not degrade and memory effect. Although with the number of advantages but still they have certain challenges and restricted them to use for specific applications. The challenges includes fast charging and discharging. In order to use super capacitors as a storage media in the battery world, one need to be able to charge them as required by the load but also discharge them slowly. The capacitors are inherently low voltage device so in order to use them operationally, they have to put them in series and make them operationally at commercial voltage. During this process they have a tendency to become unstable and it is very difficult to scale in megawatts. Balancing algorithm or balancing technology is used to stable the super capacitors during charging and discharging process. Further, mathematical modeling and simulation will be the key to success in designing of future high-energy and high-power devices (Simon and Gogotsi, 2010). Moreover, the specific energy or energy stored in kilograms of weight, which is also has been traditionally a problem and it affected form factor. Wang *et al.* (2018) reviewed the recent progress of Micro-super capacitors as a new class of high-power miniaturized electro-chemical energy-storage devices.

From the safety aspects, super capacitors can be discharge to zero volt so in case of emergency the super capacitors can discharged full energy to zero energy within seconds without any kind of damage. Secondly it does not have noxious flammable chemicals in it with no risk of thermal run away. Thermal runaway becomes the most serious safety issue in lithium-ion batteries and super capacitors (Yang *et al.*, 2018). So in case of fire one can discharge the energy completely and it acts as fire retardant. It is one of the most suitable candidates for green energy storage. Among the applications the super capacitors

- (1) Can be deployed at any scale and in any location, independent of or connected to available infrastructure.
- (2) When deployed in remote locations with no or poor grid access, can supply electricity from 100% renewable generation, eliminating dependency on fossil fuel-based generators.
- (3) Can be deployed with any combination of generation sources from exclusively renewables to a combination of renewables and fossil fuel.

Fig. 2 Schematic of super capacitors. (a) Electric double layer capacitors (EDLC) using ion adsorption and pseudo-capacitors having fast surface redox reactions. Reproduced from Jian, X., Liu, S., Gao, Y., *et al.*, 2016. Carbon-based electrode materials for supercapacitor: Progress, challenges and prospective solutions. *Journal of Electrical Engineering* 4, 75–87.

- (4) Categorized as a long-term asset due to long cycle life of the storage and long design life of the server.
- (5) Delivers reliable and stable utility grade electricity. In locations with grid access, can be deployed at mission critical facilities that depend on uninterrupted supply: Military bases, hospitals, fire and police stations, data centers, etc.

Lithium Sulfur (Li-S) Batteries

The common Li – S batteries, sulfur composite cathode, metallic lithium anode, and organic electrolyte are its main constituents (Mai *et al.*, 2014). Sulfur is the tenth most abundant element and this is actually considered as a waste by industries. Fundamentally it is cheap and can be used as a material for energy storage.

Lithium Oxygen (Li-O₂) Batteries

Two main challenges in batteries are to cut cost and improvement in performance of battery technology. As an estimation 17% of battery cost is as materials and everything else is subject to technological improvement. The other option of improvement is a new better technology. The anode lithium is possibly be a light element and comparing with air cathode make it really light and hence the advantage of its high energy density also electrochemical equivalent of metallic lithium is very high. Fig. 3 illustrates four different architectures of Li-air batteries which all assume the use of lithium metal as an anode. Namely these architectures are aprotic, aqueous, mixed aprotic-aqueous system and fully solid state architecture. Primary components are as labelled in the Fig. 3. The Spontaneously occurring solid electrolyte interface on the lithium anode are shown as dashed lines, while in case of artificial it is illustrated as a solid lines.

In lithium air battery, metallic lithium is anode, porous carbon is cathode and an electrolyte which is ion liquid. During the discharge of battery lithium ions coming out into solution and in the presence of oxygen from the air form lithium peroxide or oxide depending upon the extent to which the battery is discharged. In other words it uses oxidation of lithium at anode and reduction of oxygen at the cathode to induce the current flow. Originally proposed in 1970, it is a possible source of power for electric vehicles, hybrid vehicles and eco-friendly technologies.

Fig. 3 Various architectures of Li-air batteries. Reproduced from Girishkumar, G., McCloskey, B., Luntz, A.C., Swanson, S., Wilcke, W., 2010. Lithium – air battery: promise and challenges. *The Journal of Physical Chemistry Letters* 1 (14), 2193–2203.

The energy density (that is the amount of energy that can be extracted out of kilogram of material) of lead acid batteries is very less (40 Wh/kg), lithium ion have substantially high (around 120 Wh/kg) but lithium air batteries have exceptionally high value (1700 Wh/kg) as shown in [Fig. 4](#). So this battery is 10 times more operational than lithium ion battery having same weight.

The abundant availability of sodium makes sodium ion batteries cost-effective, which are potentially competitive with LIBs in large-scale energy storage system such as electricity grid.

Materials

[Yu et al. \(2017\)](#) suggested Polyhedral-like NiMn-layered double hydroxide/porous carbon (NiMn-LDH/ PC-x) composites as anode and activated carbon as cathode for super capacitors. [Cakici et al. \(2017\)](#) developed carbon fiber fabric/MnO₂ based hybrid materials for large-scale energy storage systems (super capacitor) applications in which MnO₂ was uniformly coated on the surface of carbon fiber fabric (CFF). The Energy storage capacity of the double layer capacitors can be enhanced by using large specific surface-area electrodes with the use of nanostructured carbon materials (graphene, nanotubes, etc.) On the other hand, the pseudo capacitors mainly use nanostructured metal oxides with the combination of carbon materials, which leads to the increase of energy storage and specific capacitance ([Cakici et al., 2017](#)). [Liu et al. \(2018\)](#) presented carbon textiles that are uniformly covered with NiCo₂-xFe_xO₄ nanotubes as electrode materials in energy storage devices. Although carbon-based materials have abundant supply and also have high surface area but the capacitance and energy density are still relatively poor than batteries and further it can be enhanced by using electrochemically active materials with high pseudo capacitance such as RuO₂, MnO₂, Co₃O₄, Co(OH)₂, Ni(OH)₂ and so forth ([Mai et al., 2014](#)). The combination of these materials has also been proposed for further improvement (enhancement of electrochemical performance is called “synergistic effect”).

Being available in different allotropes such as graphite, diamond and fullerenes/nanotubes, carbon has a rich electrochemical properties due to its mesoporous character ([Frackowiak and Beguin, 2002](#)). Moreover it has various micro-textures and a variety of dimensionality (from 0 to 3D). Further its application as an electrode material (due to its easy processability and low cost) makes carbon as a material for the storage of energy in electrochemical capacitors ([Frackowiak and Beguin, 2001](#)). Many researchers also reported the use of conductive papers as a storage device. [Pushparaj et al. \(2007\)](#) demonstrated the use of nano porous cellulose paper embedded with aligned carbon nanotube electrode and electrolyte for building various flexible storage devices such as super capacitor, battery, hybrid, and dual-storage battery-in-super capacitor devices. [Hu et al. \(2009\)](#) also suggested the use of conductive

Fig. 4 Energy densities of various types of rechargeable batteries. Reproduced from Girishkumar, G., McCloskey, B., Luntz, A.C., Swanson, S., Wilcke, W., 2010. Lithium – air battery: promise and challenges. *The Journal of Physical Chemistry Letters* 1 (14), 2193–2203.

paper (Prepared with 1D nano-materials and commercially available paper) for high-performance energy storage devices. Moreover this can be a highly scalable and low-cost solution. Nano-materials constituted by nanoparticles or Nano-architected materials although have certain challenges like difficulties in controlling the size and size distribution of the particles or clusters but have led to the development of new super capacitor technologies by significantly changing the electrode and electrolyte properties, and consequently their performance for energy storage and conversion (Arico *et al.*, 2011). Among Two-dimensional (2D) nanomaterials, especially graphene, have been in the focus of researchers due to its wide range of applications. Summarized the recent advancements of solution processed two-dimensional (2D) metal dichalcogenide (MDC) and their hybrid nano-materials for energy storage and conversion applications, which includes rechargeable batteries, super-capacitors, electro catalytic hydrogen generation and solar cells. Chaudhary *et al.* (2017) reported the development of ternary Au/ZnO/rGO nano-composites prepared with microwave-assisted hydrothermal method for high performance supercapacitor applications. Results demonstrate that Au/ZnO/rGO nanocomposites acts as an active electrode materials for electrochemical pseudo-capacitors performance and can be used for electrochemical storage devices with both high energy and power densities. The nano sized electrode materials have distinction in terms of kinetics and capacity, but it also suffer from low thermodynamic stability and high activity towards surface reactions (Guo *et al.*, 2008).

Summary and Outlook

This review has been focused on the recent advancements for new and improved electrode materials and electrochemical energy storage devices. However, the high performance electrochemical energy storage mediums has been extensively developed in past decades, with the typical characteristics such as the high energy density, high power density, thermal stability and long cycling life. The high performance electrochemical energy storage mediums with these superior parameters are required for further development. Another interesting direction would be to develop new materials for 3D printing for much improved electrochemistry, which can not only help in better fundamental understanding of hybrid technologies, but also achieve optimized device performance as a storage medium. Additionally, it is also believed that nanostructured materials will play an important role in enhancing the performance of electrochemical energy conversion and storage mediums. Besides solving various challenges in energy storage applications, the researchers from a range of disciplines will be required, and their success will contribute the development of next generation eco-friendly and sustainable energy devices.

Nomenclature

A	Area of wall (m^2)	k_{ins}	Insulation material's thermal conductivity ($\text{W/m } ^\circ\text{C}$)
C_A	Insulation material cost per unit volume (RM/m^3)	LCC	Life-cycle cost (RM)
ADH	Annual degree hours (hr)	N	Service lifetime (year)
C_e	Electricity cost (RM/kWh)	O_h	Annual operating hour of the air conditioner (hr)
$C_{t_{ins}}$	Insulation material cost (RM/ m^2)	PE_i^1	Fuel mix percentage in year i (%)
$C_{t_{uns}}$	Total energy cost without insulation (RM/ m^2)	R_{ins}	Insulation material resistance ($\text{m}^2\text{ } ^\circ\text{C/W}$)
$C_{t_{ins}}$	Total energy cost with insulation (RM/ m^2)	R_{wall}	Un-insulated wall resistance ($\text{m}^2\text{ } ^\circ\text{C/W}$)
d	Electricity price increase rate (%)	R_{wt}	Total wall resistance without insulation ($\text{m}^2\text{ } ^\circ\text{C/W}$)
E_A	Annual energy consumption of the air conditioner (kWh)	$T_{o,av}$	Annual average temperature of outside air ($^\circ\text{C}$)
EM_i	Consumed electricity in year i (GWh)	T_o	Design outside temperature ($^\circ\text{C}$)
EM_p^1	Emission for fuel type n (kg)	T_i	Design inside temperature ($^\circ\text{C}$)
h_i	Inner surface convection heat transfer coefficient ($\text{W/m}^2\text{ } ^\circ\text{C}$)	TS	Total saving (RM/ m^2)
h_o	Outer surface convection heat transfer coefficient ($\text{W/m}^2\text{ } ^\circ\text{C}$)	U	Heat transfer coefficient ($\text{W/m}^2\text{ } ^\circ\text{C}$) ($\text{W/m } ^\circ\text{C}$)
i	Discount rate (%)	x_{ins}	Insulation thickness (m)
k_n	n^{th} wall layer's thermal conductivity ($\text{W/m } ^\circ\text{C}$)	x_n	n^{th} layer of wall's thickness (m)
		x_{opt}	Optimal insulation thickness (m)
		ΔT	Difference between inside and outside design temperature ($^\circ\text{C}$)

Introduction

The global energy map is changing and the demand is increasing every day due to the industrialisation, urbanisation, technological development and population growth (Mofijur *et al.*, 2012; Ong *et al.*, 2011). Global energy demand grows by more than one-third over the period to 2035 with China, India and the Middle East accounting for 60% of the increase (Mofijur *et al.*, 2013). Worldwide the energy consumption is distributed among four main sectors namely industrial, building (residential/commercial), transportation and agricultural areas. It has been reported that currently 36% of global final energy is consumed by both buildings and buildings construction sectors which causes nearly 40% of total direct and indirect CO_2 emissions. In the United States (US) alone 65% total energy is consumed by the building sector and 42% of energy is consumed by the European Union (EU) (Wang *et al.*, 2018) themselves. However, the numbers of commercial and institutional buildings in 2050 will be three times higher than that of 2010. It is evident that the energy demand from building sector continues to rise, driven by improved access to energy in developing countries, greater ownership and use of energy-consuming devices, and rapid growth in global buildings floor area, at nearly 3% per year.

The building sector is one of the largest energy consumers in Malaysia. As a developing country, Malaysia has experienced a significant increase in energy demand (Mahlia *et al.*, 2012) and nearly 40% of consumed energy is required for building cooling and heating. The concern related to energy consumption and related CO_2 emission will be more acute as the number of houses in Malaysia is increasing every year. It has been suggested that the growth of energy consumption in Malaysia can be reduced by introducing energy efficiency systems (Mahlia, 2004; Mahlia and Chan, 2011; Mahlia *et al.*, 2002a, 2004a, 2003, 2005a,b; Mahlia *et al.*, 2010; Mahlia and Yanti, 2010; Taufiq *et al.*, 2007).

However, to ensure sustainable development by lowering the global energy demand and its negative impacts, an efficient energy usage system needs to be developed. The energy consumption of a building is mainly reliant on the properties of its envelope and the thermal performance of building walls is an important factor to improve the energy efficiency as well as to reduce the emissions (D'Alessandro *et al.*, 2016). Furthermore, correct insulation materials, its thickness and its position can play an important role to offer thermal comfort and huge energy savings. It has been reported that better thermal insulation with low thermal conductivity contributes significantly to new construction and retrofitting existing buildings.

There are many studies in the literature (Bonakdar *et al.*, 2014; Daouas *et al.*, 2010; Nematchoua *et al.*, 2017) on the determination of the impact of insulation materials on energy savings in building and environmental in some tropical countries

are discussed by [Mahlia \(2002, 2003\)](#), [Mahlia et al. \(2002b, 2004b\)](#) and [Ong et al. \(2011\)](#). But the information regarding the practical use of insulation materials in a tropical climate is very limited. Thus, this study investigated the effect of Ten type's thermal insulation materials on the energy savings and cost benefits of building walls in tropical countries. In addition, the effect of leaving air gaps in Malaysian building walls on the energy savings and cost benefits is also investigated.

Materials and Method

This study focuses on the aspect of energy savings and economy of insulation material and air gap in the building wall. Life-cycle cost analysis is utilised to evaluate the economic impact and determine the optimal insulation thickness. In the first part of the study, an insulated wall structure with no air gap is investigated and the comparison is done for the selected ten insulate in materials. The most economic insulation is determined and evaluated based on introducing an air gap. The final results of this study provided support for the decision process to select suitable insulation materials.

Material Selection

It is very important to select a good insulation material for efficient building energy conservation. There are many factors such as cost, durability, climate, availability, mode of heat transfer, installation, building orientation that need to be taken into consideration in the material selection process ([Mahlia and Iqbal, 2010](#)). In this study, ten insulation materials namely fiberglass (rigid), fiberglass (batts), urethane (rigid), urethane (roof deck), fiberglass-urethane, cellulose, extruded polystyrene, perlite, rock wool and styropor were selected and investigated. The thermal conductivity and cost of insulation data of selected insulation materials are tabulated in [Table 1](#) ([Mahlia et al., 2012](#)).

Wall Structure

The common materials for the building construction include concrete, stones and bricks and iron bars for reinforcement. Insulation in the building wall is introduced to increase the thermal resistance of the building as well as reduce the cooling loads. In the present study, the building wall construction was a sandwich type wall in which a two-piece horizontal hollow brick-layers with plaster. The insulation materials were installed on the internal side of the wall surface. The insulated wall structure is illustrated in [Fig. 1](#).

Data Collection

In this study, Malaysian commercial building has been considered because Malaysia has a tropical climate includes hot and humid. Climate data were collected from the Meteorological Department, Malaysia for a period of two years with an outdoor constant temperature between 23.7 and 31.3°C ([Malaysian Meteorological Department, Ministry of Energy, Science, Technology, Environment and Technology, 1972–1997](#)). Generally, commercial buildings are occupied from 8 am to 5 pm; thus, the average temperature and relative humidity were estimated at 29°C and 75% respectively ([Mahlia et al., 2007](#)). The effective temperature of 21°C is selected as the optimal comfort temperature for building occupants according to the data presented in [Table 2](#). Thermal comfort can be defined as the condition for satisfying the thermal environment for the inhabitants ([Olesen, 2000](#)).

Methods

The methodology of this study is divided into two sections. The first section includes the energy consumption calculation through heat transfer and the second section includes the life-cycle costs to evaluate the economic impact.

Table 1 Data for insulation materials

Insulation materials	Thermal conductivity, K_{ins} (W/m °C)	Cost of insulation, C_{ins} (RM/m ²)
Fiberglass -urethane	0.021	214
Fiberglass (rigid)	0.033	304
Urethane (rigid)	0.024	262
Perlite	0.054	98
Extruded polystyrene	0.029	182
Urethane (roof deck)	0.021	221
Cellulose	0.043	175
Fiberglass (batt)	0.045	145
Rock wool	0.043	228
Styropor	0.030	100

Correlation between thermal conductivity and the thickness of selected insulation materials for building a wall. *Energy and Buildings* 39, 182–187.

Table 2 The effective temperature for each comfort range in hot climate

Comfort range	Effective temperature F ($^{\circ}\text{C}$)
Above acceptable	Above 76 (above 24.5)
Upper acceptable	73–76 (22.8–24.5)
Optimal	69–73 (20.6–22.8)
Lower acceptable	66–69 (18.9–20.6)
Below acceptable	Below 66 (below 18.9)

Calculation of energy consumption and heat transfer

Heat loss or gain in the building is occurred due to the heat transfer through windows, walls, floor, ceilings and infiltration of air (Diamant, 1965). In this study, heat gain was considered only through the building wall. In hot weather, the heat flows from outside to inside and the indoor air temperatures are regulated by the cooling load. The total heat transfer through the wall is calculated using the following equations:

$$Q = UA(T_o - T_i) = UA\Delta T \quad (1)$$

Where, T_o and T_i are the outside and inside ambient temperature respectively, U is the overall wall heat transfer coefficient and A is the area of the wall. Thus, heat gain per unit area becomes (Mahlia and Iqbal, 2010):

$$q = U\Delta T \quad (2)$$

The U -value of a wall is depending on the thermal conductivity of the wall and the convective coefficient of any solid/air interface. The equation for U -value is (Mahlia and Iqbal, 2010):

$$U = \frac{1}{\left(\frac{1}{h_o} + \frac{x_1}{k_1} + \frac{x_2}{k_2} + \dots + \frac{x_n}{k_n} + \frac{1}{h_i}\right)} \quad (3)$$

Where h_i and h_o are the inside and outside surface convective heat transfer coefficients, k_x is the thermal conductivity for each wall layers, x_x is their thickness. Air gap in a composite wall is a confined area and air flow is restricted, therefore the convection factor in air gap can be neglected (Mahlia and Iqbal, 2010).

The insulation thermal resistance, R_{ins} can be calculated by:

$$R_{ins} = \frac{x_{ins}}{k_{ins}} \quad (4)$$

$$U = \frac{1}{\left(R_{tw} + \frac{x_{ins}}{k_{ins}}\right)} \quad (5)$$

As a result, the annual energy consumption, E_A per unit area for cooling is:

$$E_A = \frac{ADH \times q}{COP} \quad (6)$$

Where COP of air-conditioner and the annual degree hours, ADH can be calculated by:

$$ADH = \frac{O_h(T_{o,av} - T_i)}{(T_o - T_i)} \quad (7)$$

Where O_h is air-conditioner operating hours and T_i , T_o indicate temperature for inside and outside air, respectively, while $T_{o,av}$ is the average of annual outside temperature.

Finally, the annual consumed energy per unit can be rewritten as:

$$E_A = \frac{ADH \times U \times \Delta T}{COP} \quad (8)$$

Economic analysis

The present worth factor is determined in order to convert the total cooling cost over the service lifetime of N years to its present value (Hasan, 1999). The PWF can be defined as (Ghrab-Morcos, 1991):

$$PWF = \sum_{u=1}^n \left(\frac{1+i}{1+d} \right)^u = \begin{cases} \frac{1+i}{d-i} \left[1 - \left(\frac{1+i}{1+d} \right)^n \right] & i \neq d \\ \frac{n}{1+i} & i = d \end{cases} \quad (9)$$

Where i is the discount rate and d is electricity increase rate adjusted for inflation.

Therefore, the consumed energy cost per unit wall surface area is:

$$C_t = PWF(E_A \times C_e) \quad (10)$$

Where, C_e is the electricity tariff rate.

The cost of insulation material, C_{ins} is obtained as below:

$$C_{ins} = C_A \times x_{ins} \quad (11)$$

Where, C_A is insulation cost per unit volume and x_{ins} is the thickness of insulation.

Finally, the total life-cycle cost saving (TS), is the net savings from total consumed energy cost without insulation, $C_{t_{uns}}$ deducts the sum of the total consumed energy cost with the insulation, $C_{t_{ins}}$ and insulation cost, C_{ins} . TS can be expressed in the following equation (Mahlia and Iqbal, 2010):

$$TS = C_{t_{uns}} - (C_{t_{ins}} + C_{ins}) \quad (12)$$

Results and Discussion

The comparison of ten selected insulation materials based on tropical condition over a life-cycle period of twenty years has been discussed. Firstly, life cycle cost and energy saving for each selected materials have been determined and compared. In the second part, the effect of introducing an air gap in the insulation material has been evaluated.

Comparison of Selected Insulation Materials

Using more insulation, energy uses will decrease. That will lower the energy cost, but is also be beneficial to the environment. However, there is a limit when exceeding certain insulation thickness, the potential energy saving will not exhibit extra life-cycle cost saving.

Life cycle cost analysis

The calculated life-cycle cost is presented in Fig. 2. Life cycle cost savings vary from 73% to 85%/m² wall, depending on the insulation material. Styropor is the most economical option. It can save up to 84.74%/m² wall in 20 years by an optimal thickness of 0.139 m. This is because of more insulation thickness for energy saving can be installed due to the low insulation cost of styropor. Although Perlite has low insulation cost, it is not possible to achieve as high-cost saving as styropor because of high thermal conductivity properties. It Perlite has too poor in thermal resistance to retard heat flow into buildings and reduce the cooling loads. On the other hand, urethane (rigid) shows the lowest cost saving (73.05%/m²) as a result of the highest thermal conductivity cost.

Fig. 2 LCC saving by insulation thickness for each insulation materials.

Table 3 Energy saving at optimal insulation thickness

Insulation type	Energy saving at an optimal thickness (%/m ²)
Rock wool	85.69
Fiberglass (batt)	88.31
Fiberglass (rigid)	85.53
Cellulose	87.37
Fiberglass-urethane	90.28
Styropor	92.05
Urethane (rigid)	88.52
Perlite	89.44
Extruded polystyrene	89.42
Urethane (roof deck)	90.16

Energy savings

The energy saving using optimal thickness for selected material is tabulated in Table 3. Styropor shows the highest energy saving (92.05%/m²) while fiberglass (rigid) has the lowest energy saving (85.53%/m²) compared to all insulation materials.

The Effect of Introducing an Air Gap

According to the brick industry association, an air gap is introduced to improve the insulation effect by retarding the heat flow into the building. The larger air gap is desired to protect the building from heat gain, hence reduced cooling load. However, a larger air gap size will affect the construction of the building wall and reduce the occupied space of buildings. The cavity or air space between walls should be between 50 mm and 114 mm. Air spaces less than 50 mm cannot practically be kept free from mortar bridging. Air spaces greater than 114 mm do not allow the normally prescribed ties to properly transfer lateral loads. Air spaces different from these can be used, but more care in design and construction would then be required. If larger air spaces were used then additional ties and/or thicker ties may be necessary (Brick Industry Association US, 1998). Styropor is the most economic insulation materials based on the results. Therefore, it is selected for the investigation of the air gap implementation. The effect of introducing air gap on the optimal thickness, life cycle cost saving potential of styropor is discussed in the following section.

Life cycle cost analysis

When there is no insulation, by solely introducing air gap, life cycle cost saving of 38.37%/m² walls, 44.98%/m² wall, and 50.31%/m² wall can be achieved by using an air gap of 2 cm, 4 cm, and 6 cm, respectively. Increased air gap tends to have higher cost saving. Table 4 shows the life cycle cost saving after introducing an air gap for styropor. Additional life cycle cost saving of 0.64%/m² wall, is obtained by applying a 6 cm air gap on styropor insulation at optimal thickness.

Energy saving

Potential energy saving of 38.37%/m² wall, 44.98%/m² wall, and 50.31%/m² wall can be achieved by applying air gap of 2 cm, 4 cm, and 6 cm, without insulation. The effect of introducing an air gap on energy saving for styropor is tabulated in Table 5. There is no significant effect on emission reduction when applying air gap on styropor insulation at its optimal thickness. This is because cost saving is achieved by reducing insulation cost, instead of energy savings.

Table 4 Life cycle cost saving of each air gap sizes for styropor

Insulation thickness	Life cycle cost saving (%/m ²)			
	No air gap	2 cm air gap	4 cm air gap	6 cm air gap
No insulation	0.00%	38.37%	44.98%	50.31%
Optimal thickness	84.74%	85.13%	85.26%	85.38%

Table 5 Energy saving for each air gap sizes for styropor

Insulation thickness	Energy saving (%/m ²)			
	No air gap	2 cm air gap	4 cm air gap	6 cm air gap
No insulation	0.00%	38.37%	44.98%	50.31%
Optimal thickness	92.05%	92.08%	92.04%	92.06%

Conclusion

In this paper, annual energy saving and life-cycle cost are calculated for ten types of insulation material in Malaysian building walls. The results indicated that insulation material improve the life-cycle cost savings which vary from 73% to 85%/m² wall, and energy saving vary from 85–92%/m² wall. Styropor insulation material is found to be the most economic insulation material, while fiberglass shows the lowest cost-saving material. In addition, introducing an air gap in the wall is important and only 6 cm air gap without insulation improve the life cycle cost saving up to 50.31%/m² wall. There is an additional 0.64%/m² cost saving is found by introducing 6 cm air gap to a styropor insulated wall. Finally, it can be said that thermal insulation in building a wall is important as it improves energy efficiency significantly.

Energy Efficient Composite Materials

Background

Here history of materials is not related to their existence rather it relates to their functionality for human welfare. Material use started with stones well before 10,000 BC and the period was known as Stone Age. In that period human created different tools, weapons, and other commodities in crude form from stones. In the Palaeolithic era, it was realised that heavy and round objects could be easily displaced by rolling, hence, fallen trees were placed underneath large and heavy objects to act as rolling bearing for shifting goods from one place to another. It is well documented that potter's wheel was used in Mesopotamia (Iraq) in 3500 BC, at that period only wheel came into existence. The oldest wooden wheel was discovered in Ljubljana, Slovenia in about 3200 BC. It is the period when wheel was first used in chariots for transportation purpose. Later, it was replaced by spoked wheel, and for greater strength by iron rims and finally by a rubber wheel using compressed air which paved the way for automobile. Stone continues to be part of our life as a material for building and construction application. The seven wonders of the World are all of stone construction, and exhibit excellence in engineering and art. In about 3000 B.C. bronze was created by mixing tin and copper and it is called Bronze Age. Later zinc was also mixed in a small amount to make it more versatile for various applications. Though it was named gun metal but actually it was beginning of "age of alloys" and it laid the foundation of "material design". Later, it gave way to atomic energy, space flight, air travel, communications systems and microelectronic devices, buildings, vessels & commodity items, by different metal combinations. 2000 B.C. to 1100 B.C. is referred as Iron Age in which steel came into existence. Alloying of iron, heat treatment and secondary processing was used to enhance hardness, strength or toughness (Anonymous, 1906; Tylecote, 1992).

As time went by from different ages such as stone, wood, copper, iron to alloys, super alloys etc., the scientific community kept on exploring to develop new improved materials. Objective has always been to create something new or to improve existing one to have better efficiency of machines. It is well understood that metals and alloys do have limitations of properties but composites can be tailored to achieve wide range of properties to suit a particular application with better efficiency.

The range of application is very wide if we look for energy efficient materials and in one article it will not be possible to do justice while considering large number of applications. Hence, article will be restricted to energy efficient materials for limited tribological applications.

Tribological Components

Tribology is science and engineering of industrial components. The components are designed on reliability and durability criteria. In broader sense, components transmit power to achieve desired motion. Hence, the scope of wear and friction studies become wider, and depending on application aspect it can be classified as tribology of plain bearings, rolling element bearings, gears, rotary dynamic seals, space, automotive, diesel engine, rail transport, earthmoving, mining & mineral processing, marine equipment, manufacturing, magnetic storage devices, micro-electro-mechanical systems (MEMS), etc.

Applications With Conventional Materials

Sliding-Contact Bearings

Sliding-Contact Bearings are machine parts used to support moving shaft. These are designed in a way to transmit force between surfaces having relative motion. In sliding bearing, load is transferred among moving parts through sliding contact. Such bearings are also termed as plain bearings or bushings. Thrust and journal bearings are most widely used among all bearings (Bisson and Anderson, 1964; Neale, 1973; Booser, 1984; Fuller, 1984). In such bearings lubrication can be provided in any form such as gaseous, fluid or solid. Selection of material is crucial due to optimisation of properties like thermal conductivity, compressive & fatigue strength, ability to embed & conform and resistance to wear & corrosion. Moreover, the cost part cannot be ignored. Alone proper selection of material cannot stop wearing of parts for certain operating conditions but certainly delay the failure. Failure generally takes place by abrasive, adhesive or corrosive wear mechanism and or it may have combination of these mechanisms.

It's common to use unlubricated sliding bearings which result in high friction and wear loss. Though use of proper lubrication drastically reduces these losses. Lubrication regimes have a important role to play. There are three levels of lubrication:

- Boundary lubrication
- Full film lubrication
- Mixed film lubrication

In all the cases material selection which is based on metals, non-metals and their alloys is of prime importance (Ku, 1970; Neale, 1973; Booser, 1984; Fuller, 1984; Glaeser, 1992; Bhushan and Gupta, 1997). Precious metals, tin- and lead base babbitts, brasses & bronzes, cast irons, and aluminium alloys have been in wide use, whereas, among non-metals ceramics, cermets, graphites are important. Bi- & tri-metallic bearings with steel backings are also used as sliding bearing. In certain applications coated materials using different deposition techniques are also used (Ron Pike and Conway-Jones, 1992).

Rolling-Contact Bearings

Rolling-Contact Bearings have balls or rollers between two surfaces known as races or rings. The outer race is stationary and is mounted on bearing housing, while inner one is either carried by shaft or journal. The balls or rollers are held in angularity in a separator. These bearings have very less area of contact, hence, observe much less friction than sliding bearings. Due to low friction these are also termed as antifriction bearings. These bearing have very high load bearing capacity and stiffness. As the actual area of contact is very low (nearly zero), therefore, they face high contact stresses of the order of 500 MPa. (Bisson and Anderson, 1964; Neale, 1973; Booser, 1984; Harris, 1991; Zaretsky, 1992). Generally, grease or liquid lubricants are used with these bearings and in case of high temperatures or vacuum self-lubrication is essential. Rolling contact bearings generally fail by fatigue cracking/spalling leading to dislodging of large pieces from contact regions (Tallian *et al.*, 1974; Zaretsky, 1992; Summers-Smith, 1994). In cases of substantial sliding, surface damage takes place as scuffing or smearing abruptly changing adhesive mode of wear from mild to severe (Tallian, 1967; Scott, 1977).

SAE 52100 grade high-carbon chromium steel has been a standard bearing material with 58 HRC hardness. It also contains Mn, Si, Ni, Cu, and Mo in small amounts. It can work up to 200°C while high speed steels can be used up to 320°C. These steels are not suitable in corrosive media but AISI 440 C stainless steel can be used. Case hardened 4320 & 4360 AISI steels are also used in roller bearings (Neale, 1973; Bamburgh, 1980; Zaretsky, 1992; Bhushan and Gupta, 1997). In high-performance applications of high speeds and/or high temperatures silicon nitride is most suitable due to its almost three times hardness and less than half coefficient of friction of bearing steels. Further, its good fracture toughness and nature to maintain strength & oxidation resistance up to 1200°C, makes it a promising material (Bhushan and Sibley, 1982). Silicon nitride bearings are widely used in automotive, aerospace and defense industries. Silicon nitride ball bearings with steel rings called hybrid ball bearings are also used due to lower density, high rigidity, low friction and improved stiffness even though these are more expensive (Bhushan and Gupta, 1997; Harris, 1992). Though the material choice is of prime importance but lubrication aspect cannot be ignored because it:

- Forms a film between the rolling elements and raceways, rolling elements and cage etc. which minimises metal-to-metal contact, thereby, reducing friction and wear
- Contains a chemical additive that minimises wear and corrosion
- Also dissipates heat generated due to friction

Bearing failure could be caused by either of mechanisms namely adhesive wear, corrosive wear, abrasive wear, surface indentation, pitting or fatigue spalling or combination of these. Such situations arise due to inadequate supply of lubricant; hence, it is important to separate contacting surfaces effectively by hydrodynamic and elasto-hydrodynamic action (Harris, 1992).

Gears

Gears are very common machine parts, though, it looks simple but their effective design requires knowledge from several engineering disciplines. Gear designing depends on the requirements for a particular application. Depending on that geometry of gear, material, manufacturing route, heat treatment cycle, and lubricants are decided. From designing aspect resistance to scuffing & wear and reasonable strength is important. Gears are toothed wheels. These are designed to change rotation speed & transmit rotary motion from one shaft to another (Dudley, 1964; Merritt, 1971; Shigley and Mischke, 1989; Errichello, 1992). Hence, it becomes important to work on following factors:

- Geometry of gear tooth
- Kinematics of tooth motion
- Static and dynamic forces acting on gear tooth
- Physical and chemical aspect of tooth material
- Lubricant properties
- Environmental effects

Various types of gears may encounter different kind of stresses. Spur gears teeth are straight and parallel to the axis which transmit rotary motion between parallel shafts, while in helical gears teeth are not parallel to the axis of rotation and these are used for parallel and nonparallel shafts. The smooth transfer of load in helical gears from one tooth to another provides ability to transmit heavy loads successfully even at high speeds. In bevel gears rotational axes are not parallel. These are made for a shaft angle of 90° or any odd angle. These gears face Hertzian stresses just like rolling-contact bearings. Like different kind of stresses lubrication regimes are also different for gears. Overall situation provides likelihood of typical failure modes such as abrasion, corrosion, pitting, scuffing, surface fatigue, scoring, etc. Hard materials are preferred to take care of high Hertzian stresses at contact

points (Coleman, 1970; Lee and Cheng, 1991; Dudley, 1964; Merritt, 1971; Neale, 1973; Bhushan and Gupta, 1997). Gear wear is reduced by suitable heat treatments or thermochemical treatments and appropriate use of coatings can minimise wear losses in gears. Most widely steels are used as gear material in power transmission applications, however, cast iron, bronze, non-metallics, aluminium, brass, zinc, and plastics materials are also used in different applications.

When contact stresses are very high failure takes place by micro-pitting or pitting due to Hertzian fatigue. To prevent pitting in gearsets the following points are recommended (Ueno, 1980; Winter and Weiss, 1980; Shipley, 1982):

- Reduce contact stresses by load reduction or optimal gear geometry
- Use high hardness carburised and clean steel
- Use of smooth tooth surfaces
- Use of clean, dry and cool lubricant with adequate viscosity and amount

Failure also takes place by mild adhesive wear. When new gears are used first time, manufacturing inaccuracies may restrict optimum contact between the gear teeth. Adhesive wear occurs during running-in and it subsides with time. This wear is beneficial if it smoothens the tooth surfaces and increases the area of contact by removing minor imperfections. But once bending fatigue becomes possible, extent of wear is treated as excessive. It has been observed that high lubricant viscosity has maximum effect in reducing slow-speed adhesive wear (Winter and Weiss, 1980), but presence of sulphur and phosphorus increases the wear significantly. The adhesive wear in gearsets can be minimised by (Errichello, 1992):

- Smooth tooth surfaces
- Operating new gearsets first 10 h with half the load
- Avoiding sulphur & phosphorous and any other contamination in lubricants

Contamination of the lubricant by hard and/or sharp particles causes abrasive wear failure. It is common to have sand, grinding dust, machining chips, etc. in new gearboxes. It is important to drain these out. All maintenance procedures must be performed with care to prevent any kind of contamination in gearbox. Hence, to prevent abrasive wear in gearsets (Errichello, 1992):

- Contamination from new gearboxes must be drained
- Surface-hardened smooth gear teeth should be used with high-viscosity lubricants to minimise internally generated wear
- Tight oil seals should be used
- Lubricant must be changed after every 2500 h

Polishing wear may also lead to failure of gear if additives in the lubricant are chemically too reactive. It may create a good looking bright gear with inaccurate result. Anti-scuff additives form iron-sulfide and iron-phosphate films in gear teeth area having high temperatures. If the rate of reaction is too high continuous removal of the surface films leads to high polishing wear. It can be prevented by less chemically active additives such as potassium borate (Errichello, 1992).

Scuffing is localized damage by metal transfer due to solid-phase welding and fracture of sliding surfaces. It occurs in any sliding or rolling contact due to insufficient lubricating film failing to separate the surfaces. It ends up with rough, and torn surfaces. Nitralloy 135 M has very high resistance to scuffing, while stainless steels and anodized aluminium have very poor scuffing resistance. To restrict failure due to scuffing (Errichello, 1992):

- Smooth tooth surfaces should be used
- Gear teeth should be protected during the critical running-in period by coating
- Lubricants with high-viscosity and anti-scuff additives should be used
- Coolant should be used
- Gear tooth geometry should be optimised

Seals

The primary function of seals is to limit the loss of lubricants and to restrict system contamination due to environment. Seals can be static and dynamic. Static seals such as gaskets, O-ring etc. are used in static openings while dynamic seals like labyrinth, floating ring, ferrofluidic, mechanical face, lip and abradable seals are used in system with moving fluids (Lebeck, 1991). Lubrication of the sealing interface varies from hydrodynamic lubrication to zero lubrication.

In order to prevent asperity contact and to minimise wear, seal must be provided with hydrodynamic film lubrication with a thickness sufficient enough to prevent asperity contact. The seal contact pressure should be enough to balance pressure difference between the process fluid and the atmosphere. This way leakage, friction and wear all can be minimised (Iny, 1971; Snapp and Sasdelli, 1973; Mayer, 1970). When a lip seal is used on a steel shaft to seal mineral oil, as long as proper lubrication and proper pressure conditions are maintained wear is minimum and takes place only at start-stop conditions with almost infinite life of seal. However, with time abrasive particles get introduced in the oil, and act as third body wear. In this case to reduce wear the frequent change of oil is required to delay or prevent losses.

Abrasion occurs due to suspended particulates in the lubricating oil, wear debris due to inadequate lubrication, corrosion products, dust, or poor surface finish. Glass or asbestos fibers used in seals may create grooves. Adhesive wear occurs when the asperities of different surfaces observe welding and fracture phenomena. Asperities of softer material are sheared off forming

debris. Cavitation may occur when pressure difference causes bubble formation. These bubbles may expand and explode detaching the particles from the surface leading to leakage and failure (Haardt, 1974; Beatty and Hughes, 1990; Shapiro and Colsher, 1971). In different operating conditions failure may also take place by corrosion or fatigue. Hence, the main failure modes of seals are adhesion, abrasion, erosion, corrosion and fatigue (Neale, 1973; Johnson and Schoenherr, 1980; Stair, 1984). Material choice depends on design and operating conditions. In different working conditions materials such as alumina, tungsten carbide, silicon carbide, boron carbide, cemented carbides, babbitts, bronzes, graphites, thermoplastics, elastomers, Ni-resist iron, tool steel, hard-faced steel, Monel, Hastelloys, Stellite), PTFE, polyimide, or phenolic composites, silicone, fluoro-silicone have been widely used. The main prerequisites for seals are hardness and/or high abrasion resistance (Paxton, 1979; Stair, 1984; Bhushan and Gupta, 1997; Dray, 1992).

Role of seals is very crucial in systems (i) when it acts as pressure boundary between components like piston and cylinder having contrast of pressure, (ii) while preventing mixing of two incompatible fluids and (iii) when one component in contact has different nature such as static and dynamic (Dray, 1992).

Cams and Tappets

Cams and Tappets are widely used in engineering systems like automotive valve trains or textile machines to transform reciprocating sliding motion to rotary motion or vice versa. Contacts are generally points or line but they become rectangular and elliptical contact areas with load conditions. There is mix-up of rolling with sliding motion in rolling direction. These also wear in very similar modes those of gears. These may encounter mild adhesive wear, abrasive wear or scuffing due to fatigue wear (Neale, 1973; Lee and Cheng, 1991). The wear of cams and tappets could be minimised by hard material or surface hardening of steels by coating etc. Grey hardenable cast iron with Cr, Mo, and Ni is a commonly used tappet material in automotive applications. Hard coatings of titanium nitride/carbide by PVD and CVD technique can be used to minimise coefficients of friction and wear.

Piston Rings

Piston Rings act as sealing agents to lubricants in reciprocating rods, pistons, piston plungers, etc., inside cylinders. These are placed in the grooves of the piston to act as moving seal between the piston and the cylinder bore to retain lubricants intact. There are two types of piston rings i.e., compression and oil-control. Compression rings are used close to top portion of the piston to restrict downward movement of gases from the combustion chamber while oil rings are placed below compression rings to prevent the spilling of excess lubricant into the combustion chamber (Neale, 1973). Piston ring material should have low friction coefficient with mating surface having good resistance to wear and scuffing, good running-in wear behaviour, tolerance to marginal lubrication and fast changes in environmental conditions. Its performance should be consistent with reliability and low cost.

Grey cast iron is widely used for compression and oil rings. In the heavy-duty engine applications, chromium molybdenum iron, spheroidal graphitic iron, malleable iron and even some ball-bearing steel are also used. Chromium coated rings are used to improve resistance to corrosion, oxidation and wear. With this friction is also reduced. Plasma-sprayed Mo, Mo-Cr- Ni alloy, and chromium oxide have also been used to improve scuffing resistance (Neale, 1973; Scott *et al.*, 1975; Taylor and Eyre, 1979; Ting, 1980; Bhushan and Gupta, 1997). To increase cylinder liner strength Ni, Cr, Cu, Mo, Ti, and V are added in grey cast iron. Use of steel cylinder liners have added advantage that the walls can be made much thinner. In order to have high hardness to counter scuffing they also need hard Cr plating. But to keep friction coefficient low Cr plated liners should not be used against Cr plated piston rings. In recent years, Al-Si cylinder liners have replaced other liners due to lightweight and superior properties (Taylor and Eyre, 1979; Ting, 1980). Non-metals are used for unlubricated piston rings to avoid metals tendency to weld under dry sliding conditions (Scott *et al.*, 1975; Fuchsluger and Vandusen, 1980). Plastics, carbons, and ceramics are extensively used non-metals.

Brake

Brake lining material used for brake systems are termed as friction materials. These are needed for different grades of vehicles such as passenger cars, drum and disk brakes for light or heavy trucks etc. Wear aspect of brakes is more sensitive to road conditions rather than friction of brake. These systems have to face high pressure as well as temperature. Flash temperature may go as high as 1000–1100°C. Internally expanding shoes with brake linings are used in drum while disk brakes use shoes that load a much smaller portion of disk rubbing surface. Disk brakes cool faster due to larger exposed surface but are more vulnerable to contamination. Three types of friction materials such as organic, metallic, and carbon have been in use. Asbestos, non-asbestos with fibers, semi-met organics, copper or iron based, sintered bronze and mullite, sintered iron with graphite, have been used in lining of automobiles. Brakes need to operate under different conditions. Heavily loaded automobiles on steep slope need hard brake while on highways there is minimal brake usage. In all cases brakes should be reliable and these should not get affected by environment and working conditions (Anderson, 1992).

Other Applications

Tribology of magnetic storage devices, automotive, railroads and aircrafts parts with relative motion are of prime importance (O'Connor *et al.*, 1968; Neale, 1973; Peterson and Winer, 1980; Booser, 1983; Bhushan, 1996, 2001; Bhushan and Gupta, 1997). Internal combustion engines which are backbone of automotive industries are almost perfect choice for use in automobiles (Rogowski, 1953; Taylor, 1966, 1968; Crouse, 1970; Judge, 1972; Heywood, 1988). In IC engines, fuel is burned and energy produced provides linear reciprocation motion to piston in its cylinder and by connecting rod to crankshaft by rotating motion. The crankshaft attached to the drive shaft provides power to wheels for movement. Nowadays, four stroke engines are common, however, some two stroke engines are also used (Rogowski, 1953).

An automobile engine is composed of number of parts and these parts face different environment and working conditions, accordingly the material choice is made. Cylinder blocks, piston, piston rings have already been discussed. Among other parts, crankshaft is made from forged steel/nodular cast iron. Forged steel or hardenable irons are used for cams, tappets, rocker arms, and also for camshafts. Forged alloy steel works well for valves. While connecting rod bearing are made from copper alloys, tin or lead babbitts and aluminium alloys. Above all the proper lubrication is key to long life of the engine (Chamberlin and Saunders, 1983; Heywood, 1988).

In last thirty to forty years serious efforts have been made to reduce emissions and improve fuel economy to meet stringent legislated emissions norms and Corporate Average Fuel Economy (CAFE) standards. These include (Kovach *et al.*, 1982; Davis, 1992):

- Reduction in vehicle weight and to reduce aerodynamic resistance improvement in exterior
- Downsizing of engine to reduce the power-to-weight ratio
- Design improvements with a view to improve efficiency with weight saving
- Drive-train improvements such as friction losses
- Advanced exhaust system to meet emission norms
- Maximizing fuel economy with minimum emissions
- Reduction in chassis friction and tire rolling resistance
- Use of lightweight, durable ceramics and ceramic coatings

Further, fuel economy goals have led to improvement in designing to achieve improved tribological performance. Studies indicate 1%–2% fuel economy improvement in four-cylinder engine with 6.9 kPa mean effective pressure reduction in engine friction. In order of importance major engine friction components are piston ring assembly, valve train, crankshaft bearings, oil pump etc. (Kovach *et al.*, 1982).

In all reciprocating engines some kind of lubricating oil is used. Viscosity of the oil is important issue. If oil with proper viscosity is not chosen or oil gets deteriorated during service, it causes wear to pistons cylinders/ cylinder liners, piston rings, camshafts, valve trains, etc. Water vapour generated due to combustion carries corrosive gases. If these gases are settled on engine parts, they readily form acids and cause severe corrosive wear. Other modes of wear such as adhesive wear and scuffing in cylinder liners and piston rings, abrasive wear in cams, tappets and rocker arms, and pitting due to fatigue wear in cams and tappets may also take place (Lyman, 1961).

In IC engines, piston and piston ring assembly contribute largest share in terms of wear and friction losses and it is almost 25%–75% of total engine losses (Lichty, 1951; Pinkus and Wilcock, 1971; McGeehan, 1978). Hence, there has been a shift from steels to aluminium silicon alloys (Kearney, and Rooy, 1990).

Energy Efficient Materials

Advanced composite materials have proven capability over conventional materials to an extent that these have been accepted in a number of engineering applications. Advanced polymer-matrix composites were judged as potential industrial material in 1940–41 when fiber-reinforced plastics were examined for aircraft applications at Wright-Patterson Air Force Base and aft fuselage of the Vultee BT-15 trainer aircraft was designed and fabricated in composites. It proved to be about 50% stronger than existing construction. Since then, advanced composite materials have found large number of applications in aerospace, space, marine, automobiles, sports, recreation equipment specially to enhance the performance. In last 60–65 years, scope of composites has increased tremendously and it is getting widespread & diverse usage in all walks of life (Hunt, 2001).

Production of metal-matrix started in 1970s and since then these have also gained importance even in specialised applications like space shuttle, Hubble telescope, aerospace, automobile parts brakes, drive shafts, and cylinder liners. Their tailoring capability has also increased their scope in electronic packaging and thermal-management applications. Market trends suggest growth in MMC market and cost cutting is indicative of bright future (Hunt, 2001).

CMCs are proving their worth in applications like cutting tool inserts and wear-resistant parts of aerospace and military equipment including engines and energy-related applications. Though these are high performance but presently are very expensive. However, their stability at high temperature and high corrosion resistance has made them attractive in aerospace and industrial sectors (Hunt, 2001).

For last twenty years MMCs have established themselves in commercial production of automotive parts due to combination of properties like high specific stiffness, good wear resistance and light weight along with improved high-cycle fatigue resistance (Allison and Cole, 1993; Hunt, 2001). Though the cost part is still higher for discontinuously reinforced aluminium (DRA) but with time wider applications of this technology with performance improvements and new processing ideas will cut down the cost. Tables 1 and 2 provide comparison of mechanical and wear properties of some AMC and corresponding alloys. Improvement in properties is evident on incorporation of reinforcement but ductility part is not very satisfactory.

Applications of Energy Efficient Materials in Engines

Pistons

During service pistons have to go through extreme dynamic thermal and mechanical conditions. These must be capable to resist cyclic mechanical loading even at high frequencies of about 100 Hz, which means they must have excellent fatigue resistance. Maintaining highest degree of combustion pressure requires tight tolerance of piston with the cylinder and piston material should also be able to withstand ring groove pounding. Further, dynamic strength with excellent wear resistance is important for long life. Piston material should be able to resist temperature of about 300°C without deformation of the dome. To minimise thermal stresses caused by thermal gradients and thermal cycling high thermal conductivity is desirable. Also the coefficient of thermal expansion of piston top plate and ring groove region must be comparable to cylinder (Kevorkijan, 1999; Hunt, 2001).

Production of diesel engine pistons made up of aluminium matrix composite (AMC) by Toyota Motors, Japan was a major breakthrough which was brought into commercial production by Japan in 1983 (Donomoto *et al.*, 1983). These pistons consisted of chopped fiber preform only in the ring groove region which was very prone to wear and thermal fatigue. The selective reinforcement of Al-alloy provided remarkable improvement in wear resistance. Permanent die mould was used to place chopped fiber preform and infiltration technique was used under pressure with molten metal to prepare aluminium matrix composite pistons. The squeeze casting technique provides high quality parts at low cost. With this technique high production rate of 100,000 parts per month could be maintained (Kevorkijan, 1999). The important feature is that the low coefficient of thermal expansion of AMC which also permits redesigning of piston with tight tolerance. This overall change has led to high combustible pressure with improvement in heat transfer properties (Rittner, 2000). The decreased density of piston with AMC also provides improved performance. The single step squeeze casting process, with reinforced top plate and ring groove material has also reduced overall cost as compared to earlier one. Though, on unit basis the cost of AMC seems to be higher but overall cost reduction is achieved due to selective reinforcement and simple technique of production to which performance improvement is an added advantage.

The use of metal-matrix composite piston with selective reinforcement has not been considered widely in U.S. market because in North America size of diesel engines is larger and operational speeds are lower. As a result, fatigue and wear requirements are not very stringent, and so the advantages are not as compelling. Nonetheless, metal-matrix composites pistons provide a strong advantage in Asian and Western European designs, and continued growth is expected in this area. For example, Mazda Ford Motor Company introduced a selectively reinforced piston produced by a low pressure die casting process in 1998 (Rittner, 2000). SiC whisker/particulate reinforced aluminium forgings in racing engine applications are few other piston applications. Lower coefficient of thermal expansion of the MMC reduces clearances between the piston and cylinder wall. In certain cases, an order of magnitude reduction in the specified clearance may be possible (Rittner, 2000). MMC pistons have exhibited better performance as compared to conventional hypereutectic aluminium-silicon alloys in drag racing bikes (Harrigan, 1994; Hunt, 2001).

Cylinder Liners

Increased applications of aluminium/aluminium alloys engine blocks has made it imperative to have protective cylinder liners. Many of the reasons fall in line with aluminium/aluminium alloys pistons use as have already been discussed in previous section. Since very beginning cast iron has been most widely used material for inserts as well as for engine blocks due to good wear resistance with high performance. Even today, it holds the largest share. Now primary considerations are changing in order to improve efficiency which requires materials with high thermal conductivity and low density. That has caused switching over of liner materials from cast iron to aluminium alloys/composites. Honda Prelude 2.3 liter engine brought industrial revolution for AMCs cylinder liners in 1990 (Hamajima *et al.*, 1990). The AMCs cylinder liners were produced by infiltrating molten aluminium in hybrid preform of carbon and alumina while pressure squeeze casting engine block. With this process one also gets rid of need of separate liners and number of assembling steps as well as parts to be assembled are also reduced (Hunt, 2001).

Introducing AMCs in this application brought about a dramatic weight reduction of about twenty percent with improved wear resistance as compared to cast iron that definitely improves engine efficiency (Kevorkijan, 1999). Further, better thermal conductivity of AMCs also allows lower operating temperatures and extended engine life. It is also important to note that AMCs liners are much thinner as compared to cast iron liners that increases engine displacement. Large number of such engines have been produced so far. Honda has introduced AMCs liners even in their sports edition S2000, in Porsche Boxter and premium version of Acura NSX (Rittner, 2000). Engine of Toyota Celica also introduced AMCs liners and large number of units are on the road. High performance bikes of Honda are also using MMC liners (Kevorkijan, 1999; Hunt, 2001).

Valves

Working of intake and exhaust valves is very crucial in automotive engines. They coordinate the transportation of the air-fuel mixture for combustion as well as exhaust gases. In this course of action, they have to face high frequency mechanical loading, hence, good fatigue properties are very important. The valves have to go through very adverse environment, hence, requires good sliding wear resistance in valve guide. The neck faces the maximum stress due to high gas temperatures of about 900°C in exhaust valve region so requires high creep resistance. Further, exhaust valve also requires good oxidation resistance due to oxidizing compositions of the gases. Finally, the valve also undergoes hammering forces at high frequency which could result in galling/adhesion on the valve seat so it is important to have resistance against galling. Typically, low cost austenitic steels are used for automotive valves applications so these have relatively high mass. Functioning requires high spring forces so as to maintain continuous contact between the valve follower with camshaft lobe. The high rpm requires good amount of spring mass. The high force due to spring causes high degree of friction force on the cam, tensile stress at neck, and the contact forces at cylinder head. It results in loss of energy required to compress the springs and overall fuel efficiency is decreased.

Toyota Altezza 2.0 liter I-4 engine was the first one to replace austenitic steel valves by discontinuously reinforced titanium (DRTi) composite in 1998 (Froes and Jones, 1999). This DRTi was prepared by a powder metallurgy route using powders of titanium hydride, matrix alloys, and titanium di-boride (Saito, 1995). All powders were blended thoroughly, pressed in die and finally sintered. During sintering TiB₂ reacted to form stable titanium mono-boride. Homogenization and densification also took place during sintering step. Sintered billets were extruded followed by upset forging to be processed into valves. Ti-6Al-4V and Ti-6.5Al-4.6Sn-4.6Zr-1Nb-1Mo-0.3Si alloys were used for intake and exhaust valves respectively (Froes and Jones, 1999; Saito, 1995). Endurance testing at high rpm of 10,500 is also part of rigorous certification. Since the introduction of the Altezza, large number of DRTi valves have been produced and no defective units were reported. A set of DRTi valves reduces weight by about 40 percent i.e., about 270 g (Froes and Jones, 1999). In addition, including valve spring mass total engine weight reduction is around 380 g. With these composites, cam contact frictional forces and the energy required to compress the springs are also reduced. Initially, the cost of the DRTi valves was about twice as compared to steel and likely to decrease with volume of production i.e., with full-scale production. Yamaha Motor Corporation also took up DRTi valves in their large volume motorcycles production (Hunt, 2001).

Pushrods

Cylindrical pushrods are used to transfer motion from cam to the valve train in OHV engines. An eight-cylinder OHV engine has sixteen pushrods of ultra-high-strength steel. Pushrod essentially transfers desirable motion from cam to valves. High engine rpm limits behaviour of engine which includes pushrod flexure, valve toss or lofting as a result of contact problem. Flexure, lofting, and valve bounce affect engine performance, whereas, severe vibrations limit the life of valvetrain components, especially springs. These problems can be overcome by using low density and high damping capacity materials (Hunt, 2001).

In recent years, conventional 4340 steel pushrods materials has been replaced by fiber-reinforced aluminium matrix composites are now used in high-performance OHV racing engines for pushrods. The 60% of Nextel 610 Al₂O₃ fibers is infiltrated with an

aluminium matrix. 3M Corporation has produced this material for producing hollow pushrods of different diameters. In these pushrods fibers are axially aligned along the pushrod length. Ends of the AMC tubes are bonded with hardened steel end caps. These aluminium composite pushrods have double the damping capability along with 25% superior bending stiffness while comparing with conventional 4340 steel pushrods (Mendelson, 1996). Further, less than half density of AMC as compared to steel increases the engine speed by nearly 250–400 rpm before valve bounce starts. Superior damping capacity of AMC pushrods improves the spring life by six times (Mendelson, 1996). Higher life of valvetrain springs also provides cost benefit. Further benefits can be achieved by optimisation of cam design (Hunt, 2001).

Connecting Rods

There has been a focus on improvement in drivetrain components, especially connecting rod (Harrigan, 1994). The secondary shaking forces which are mostly observed in small engines are minimised to a larger extent by mass reduction of connecting rod/piston assembly. In addition, lower reciprocating loads also have lesser load effects on crankshaft and less friction losses. This improves performance with increased fuel efficiency (Allison and Cole, 1993). It is important to note that every unit of weight reduction from the connecting rod helps to reduce almost seven times from supporting load (Rittner, 2000). MMC connecting rods applications in high volume vehicles have not yet been introduced because getting an MMC with combination of low cost and high-cycle fatigue performance has been difficult so far. Though hot forged AMC connecting rods have successfully been produced and tested but with reasonably high cost of production, hence, further cost reduction is required (Hunt, 2001).

Brake System Applications

High thermal conductivity and excellent wear resistance of AMCs offer them as a very useful replacement to cast iron in brake system applications. AMCs can provide 50%–60% weight savings in disk brake rotors and brake drums. The weight reduction is unsprung, hence, inertial forces are also reduced, and that further, reduces fuel consumption providing an additional benefit. AMC rotors also increase acceleration and reduce braking distance. It is also reported that AMC rotors have less brake noise and wear, and as compared to cast iron rotors they provide a uniform friction over the entire testing sequence (Allison and Cole, 1993). Aluminium matrix composites brake rotors and drums can be successfully produced by gravity casting method. Aluminium-magnesium and aluminium-silicon alloy matrices have been used with 20 vol% of SiC and/or Al_2O_3 particle reinforcements. Several automobiles companies are using AMC brake parts. The Lotus Elise used four discontinuously reinforce aluminium brake rotors in vehicle and Plymouth Prowler has also used it for rear wheels. Discontinuously reinforced aluminium rotors have attracted lightweight automobiles makers and are used in few editions of Volkswagen and Audi. In addition, now number of electric and hybrid vehicles are also using AMC brake components (Hunt, 2001).

Discontinuously reinforced aluminium brake rotors are now being used in trains such as Inter City Express (ICE), high-speed trains, etc. MMCs brake discs are also used in ICE-1 and ICE-2 train. Application of higher-priced AMCs in automotive racing applications is also in practice, where improved performance is important. Brake calipers for Formula 1 race cars produced from a 2124/SiC/ 25p AMC provide much less displacement, high leverage, and much faster stops, due to high stiffness of the material (Hurley, 1995). AMCs brake pads are also used in conjunction with the Porsche ceramic-matrix composite brake rotors (Hunt, 2001).

Driveshaft Applications

AMCs provide higher specific stiffness in the driveshaft as compared to conventional materials. Currently driveshafts have restriction of speed at which shaft may become dynamically unstable irrespective of material used. This critical speed of the driveshaft depends on the specific stiffness, length and also on outer and inner radius. There are vehicles which have packaging constraints and increased driveshaft diameter is not possible. AMCs may provide desirable solution in the form of longer driveshaft lengths at a given diameter, or vice-versa. This situation is generally faced in large passenger or luggage carriers, where due to length restrictions, two-piece driveshaft has to be used. So, replacement of two piece driveshaft by single DRA driveshaft provides a direct reduction in weight as well as cost. Further, it also reduces weight and cost associated with the support structure used for two piece driveshaft, and reduces the mass needed for corrective counterweights as well as for balancing. Around 9 kg of weight is decreased (Rittner, 2000). Hence, driveshafts of 6061/ Al_2O_3 produced by stir casting and with subsequent extrusion into tube have been used. DRA driveshafts were introduced in some versions of Chevrolet and GMC pickup trucks. Later, DRA driveshafts became standard for Chevrolet Corvette. AMC driveshaft are also used in police interceptor version of Ford (Hunt, 2001).

Other Applications

AMCs are widely used in number of application such as brackets, pulleys, brake calipers, pump housings, turbocharger & supercharger compressors, and suspension systems (Allison and Cole, 1993). In addition, these are also used in suspension pushrods, clutch parts,

rockers, gearbox and other engine parts (Hurley, 1995). Discontinuously reinforced titanium may also be considered for some of the applications. 6061/Al₂O₃ drawn wire has been used in manufacturing snow tire studs. In Finland, MMC tire stud jackets have been successfully applied since 1990s, and represent an annual market of about 150 metric tonnes (Rittner, 2000; Hunt, 2001).

Conclusions

Growth of MMC/AMC market has been appreciable in last few decades particularly in automotive sector. Number of important applications specially performance oriented have emerged due to weight saving because benefits have over powered component cost. Performance has improved drastically due to better thermal properties & wear resistance and low coefficient of thermal expansion. But still there is need of new materials which could exactly fit into the application so that larger volumes could be generated for cost cutting. Further, for market growth stern environmental emission norms and fuel efficiency part needs to be given proper attention so that growth rate in existing applications could be improved and new avenues could be opened-up.

From last few decades, possibility of MMCs is also being explored in applications related to commercial and military aircrafts such as aero-propulsion systems and in aeronautical subsystems. Newly developed MMCs are also paving way for numerous structural and thermal management system applications. The excellent combination of specific strength with stiffness relative to existing structural materials is putting MMCs in driving seat for several aeronautical applications. DRAs and DRTi have gained importance due to high specific stiffness, fatigue resistance, damage tolerance, and durability. In terms of life cycle, MMCs also provide significant cost reductions that could provide them a wider platform from application point of view.

Environmental Analysis Waste Management Model

Dalibor Petković, University of Niš, Pedagogical Faculty in Vranje, Partizanska, Vranje, Serbia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Flood risk and waste management has come under serious consideration by many different groups in recent times. The creators' group originates from a software engineering foundation, and especially from the range of information administration and investigation. It is elusive data and current examination chips away at information administration and investigation for flood risk and waste assessment. One of the principles is that such works have been distributed in an extensive variety of discussions (Saito, 2014; Kenley *et al.*, 2014). Consequently, we chose to tackle the errand of finding and sorting out this information so as to uncover the best in class research. We concentrated on different sources, extending from diary distributions to government reports, and met with neighborhood flood and waste management authorities, to think of an arrangement of future examination headings for researchers – particularly from the ranges of information administration and investigation – that will significantly advantage flood risk and waste management groups. That is, we endeavor to extend fundamental research and practice in this area (Abosuliman Shougi *et al.*, 2014). The Federal Emergency Management Agency (FEMA) classifies disasters as Natural (e.g., earthquakes, hurricanes, floods, wildlife fires etc.) or Technological (e.g., terrorism, nuclear power plant emergencies, hazardous materials etc.) (Rieu-Clarke, 2018). Other order plans exist, yet whatever the reason, certain components are attractive for administration of all disasters:

- Prevention,
- Advance warning,
- Early detection,
- Analysis of the problem, and assessment of scope,
- Notification of the public and appropriate authorities,
- Mobilization of a response,
- Containment of damage,
- Relief and medical care for those affected.

Further, flood risk and waste management can be separated into the accompanying four stages: (a) Preparedness; (b) Mitigation; (c) Response; and (d) Recovery. Mitigation efforts are long-term measures that attempt to prevent hazards from developing into flood risk and waste altogether, or to reduce the effects of flood risk and waste when they occur (Schanze *et al.*, 2006; Wang *et al.*, 2015).

Flood Risk and Waste Data Management and Analysis Challenges

The significance of opportune, exact and successful utilization of accessible data in flood risk and waste management situations has been broadly talked about in writing. Data administration and handling in flood risk and waste management are especially testing because of the one of a kind mix of qualities (individual attributes show up in different spaces also) of the information of this area (Kar *et al.*, 2015; Chandanala *et al.*, 2013). The information that are accessible for flood risk and waste management comprise of the accompanying:

- News articles/declarations: these are mostly message information with extra characteristics on time and area, and so forth.
- Business reports,
- Remote detecting information,
- Satellite symbolism information and other interactive media information like video.

The Information Science in Flood Risk and Waste Management

The administration of flood risk and waste management information includes the incorporation of different heterogeneous sources, information ingestion and combination. Information may have static or spilling nature. The data investigation of flood risk and waste management information includes the use of all around concentrated on data advancements to this one of a kind space (Jacobsson *et al.*, 2011; Neal *et al.*, 2012). The information examination advancements that we will audit for surge hazard and waste – related circumstances are:

- Information extraction,
- Information retrieval,

- Information filtering,
- Data mining,
- Decision support.

Flood Risk and Waste Management Workflow

There are distinctive sorts of groups that require flood risk and waste data management devices and frameworks to cover the present circumstance, offer foundation and asset information, and trade other crisis interchanges (Chang *et al.*, 2012). From the point of view of the crisis administration group, authoritative performing artists incorporate the province crisis administration workplaces, cooperating offices like police and fire offices, transportation offices, utility divisions, and other basic private base like statewide vitality organizations. Crisis administration divisions take after occurrence charge frameworks benchmarks that gives conventions and procedures to control, coordination and correspondence among the aforementioned offices with purview that normally react to a flood risk and waste occasion. In a substantial scale flood risk and waste, an administration framework records close continuous circumstance reports from several sources. As recommended by occurrence summon frameworks, common reports incorporate an episode activity arrangement and circumstance report (Dagdeviren *et al.*, 2015). These reports are produced by the partaking organization and area division and give data concerning the objectives of the reacting office amid the reporting period, the moves made to accomplish these objectives and what was really accomplished. For instance, when the province crisis operations focus is actuated ahead of time of a danger, the provincial water administration office may report in an occurrence activity arrange for that it is checking precipitation and channel levels to moderate flood hazard while reporting in the circumstance report what the recorded precipitation and waterway water levels are and how that may influence the group (Sarigiannidis *et al.*, 2015). The branch chief audits and compresses these reports from every organization and produces a synopsis report that is sent to the operations executive. The operations executive joins every branch reports to create a general circumstance report for the occurrence authority. Apparatuses are utilized to record such reaction and recuperation activities to apply and get government flood risk and waste recuperation stores. Different correspondences components are utilized to transmit and report situation status, for example, messages, mailing records, faxes and even paper. For the private division, keeping up a business progression plan safeguards the association is considering the dangers that may hinder the coherence of operations and characterizes particular activities to moderate these dangers (Horita *et al.*, 2015). Taking into account the sort of flood risk and waste occasion and the measure of exertion contributed, the business coherence arrangement gives direction on what steps the business progression group will take in view of the calamity's period occasion. Business congruity groups are dependable to set up the proper interchanges and reports on situation status and readiness/reaction measures endorsed by the business coherence plan to administration and workers. Workers may be required to overhaul contact data and give operational status, sellers contracted for extraordinary debacle recuperation administrations are put on stand-by, and unnecessary hardware is moved out of hurt's way (Wadey *et al.*, 2015).

Data Integration in Flood Risk and Waste Management

Information joining is the procedure of consolidating information dwelling at diverse sources and furnishing the client with a bound together perspective of these information. This procedure rises in an assortment of circumstances both business and investigative. The issue of information combination turns out to be more basic as the measure of information that should be shared increments. By information ingestion, we mean the procedure of embedding to a framework information, which is originating from various heterogeneous sources. Adaptability is a vital issue in information ingestion, since the stream of data may be high amid the season of a basic occasion (Mason *et al.*, 2014).

Flood risk and waste data are to a great degree heterogeneous, both fundamentally and semantically, which makes a requirement for information joining and ingestion with a specific end goal to help the crisis administration authorities in quick surge hazard and waste recuperation at whatever point disasters happen. Flood risk and waste information to be gathered and incorporated for examination and administration can be:

1. Information, for example, episode activity arrangements and circumstance reports;
2. Damage examination reports;
3. Geographic information and open/conclusion status about roadways/parkways/spans and other framework;
4. Logistics information about vehicles, conveyance times, and so on.
5. Communication and message information;
6. Financial information expected to deal with the gathering and dissemination of gifts;
7. Data in sites.

All these information are in a wide range of configurations, have changed attributes, and are accessible from distinctive sources. Further, such information is regularly questionable. The accessibility of such information represents a test for the outline and improvement of compelling techniques for information obtaining, ingestion, and association. The way to get understanding and information from the heterogeneous surge hazard and waste-related information sources is to distinguish the relationship of

information from different sources. Henceforth, advancements are required for information joining and ingestion so it is conceivable to question disseminated data for flood risk and waste administration (Schlafer *et al.*, 2015).

Solutions for Data Integration

To have the capacity to handle the heterogeneous flood risk and waste information from various sources and proficient arrangements are expected to address the information incorporation and ingestion issues (Penning-Rowsell and Johnson, 2015; Vinke-de Kruijf *et al.*, 2015). The arrangements can be classified into three primary segments that cooperate with each other, and association coordination and correspondence. As appeared in Fig. 1, the surge hazard and waste administration information spaces are built up to get, ingest, sort out, and speak to the heterogeneous information. Once the information spaces are set up, the cosmology and semantic Web segment and the association coordination and correspondence part interface with one another to conquer the issue of semantic heterogeneity and to guarantee the ideal procurement of flood risk and waste-related data for quick choice making in a profoundly planned way (Neuhold, 2013).

Information Extraction in Flood Risk and Waste Management

Information extraction (IE) is the order whose objective is to consequently concentrate organized data, i.e., sorted and logically and semantically all around characterized information from a sure area, from unstructured machine-comprehensible archives. More often than not, the objective is to populate tables, given an arrangement of content reports (Tran *et al.*, 2008).

Information Retrieval in Flood Risk and Waste Management

Information retrieval is the art of hunting down archives important to a client question. The inquiry is generally communicated as an arrangement of watchwords, and the reports are returned as a positioned rundown, requested by diminishing significance. In conventional data recovery, reports are positioned in view of a positioning capacity, that is, a capacity that relies on upon the term recurrence and the backwards archive recurrence of the inquiry terms in the records. Term recurrence indicates the quantity of events of a term in a report – higher term recurrence prompts higher score – and the backwards record recurrence is corresponding to the number's opposite of archives that contain the term – higher the reverse record recurrence is better in light of the fact that it implies that the term is more occasional in the information.

Information Filtering in Flood Risk and Waste Management

Information filtering framework is a framework that expels excess or undesirable data from a data stream utilizing (semi) automated or automated systems preceding presentation to a human client. Its primary objective is the data's administration overburden and addition of the semantic sign to-clamor proportion. Data separating is a capacity to choose helpful or intriguing data for the client among a lot of data. When all is said in done, data separating frameworks channel information in view of (a) the similitude between a client profile and the printed substance of an occasion and (b) the client pertinence criticism, that is, if a client likes an occasion then comparable occasions ought to additionally be sent to that client. Data separating has numerous likenesses to data recovery. The key contrasts are that (an) in data sifting the information is spilling and (b) in data separating the inquiry is the client profile.

Fig. 1 Components of data integration for disaster data management.

Data Mining in Flood Risk and Waste Management

Data mining or learning disclosure is the nontrivial extraction of certain, beforehand obscure, and conceivably valuable data from extensive accumulation of information. Practically speaking, information mining alludes to the general procedure of removing abnormal state learning from low level information in the connection of extensive databases. To efficiently survey information mining exploration in flood risk and waste administration, we utilize the structure which comprises of an iterative arrangement of the accompanying steps: information administration, information preprocessing, information mining undertakings and calculations, and post-handling. The information administration is extraordinarily identified with the execution of information mining frameworks. Next, information preprocessing, is a critical stride to guarantee the information quality and to enhance the proficiency and simplicity of the mining procedure. True information in surge hazard and waste administration tend to be inadequate, uproarious, conflicting, high dimensional and multi-tangible and so on and consequently are not straightforwardly suitable for mining. Information preprocessing more often than excludes information cleaning to uproot boisterous information and anomalies, information joining to incorporate information from different data sources, information decrease to diminish the dimensionality and many-sided quality of the information and information change to change over the information into suitable structures for mining, and so on. Third, information mining assignments and calculations, which are the center of this area, are fundamental strides of learning disclosure. There are a wide range of information mining assignments, for example, affiliation mining, exploratory information examination, characterization, grouping, relapse, and substance recovery and so forth. Different calculations have been utilized to do these assignments and numerous calculations could be connected to a few various types of undertakings. At last, we need post-preparing stage to refine and assess the learning got from our mining strategy. For instance, one may need to streamline the separated learning. Additionally, we might need to assess the extricated information, imagine it, or just record it for the end-client. We may translate the information and join it into a current framework, and check for potential clashes with already actuated learning.

Decision Support in Flood Risk and Waste Management

Decision support frameworks are a particular class of data frameworks that backings business and authoritative choice making exercises. Specifically, an appropriately composed choice emotionally supportive networks is an intuitive programming based framework expected to help leaders arrange valuable data from assorted information sources and/or plans of action to distinguish and take care of issues and decide. The essential parts of a choice emotionally supportive networks incorporate (1) the information administration segment, (2) the model administration segment, (3) the learning motor, (4) the client interface, and (5) the user (s). Fundamentally, the information administration part stores data from different sources including association's information storehouses and outer information accumulations. The model administration part handles representations of semantic occasions and circumstances and gives different enhancement models, scientific and information mining apparatuses. The learning motor deals with the area information and in addition the information created by different models and apparatuses in the model administration part. The information motor can likewise give deduction abilities and web search tools for learning designing. The client interface permits clients to collaborate with the framework and handles the dialog.

Components of Flood and Waste Management

Based on the definition of flood risk and waste management, three tasks with specific components can be used for structuring the management activities ([Fig. 2](#)). The main tasks are:

- Flood risk and waste analysis,
- Flood risk and waste assessment and,
- Flood risk and waste reduction.

Flood risk and waste analysis provides information on previous, current and future flood risk and waste, flood risk and waste assessment deals with their perception and evaluation and flood risk and waste reduction is dedicated to interventions with a potential to decrease the flood risk and waste. To achieve the aims of each task certain components are required. They range from hazard determination to the specification of post-flood interventions ([Neuhold and Nachtnebel, 2011](#); [Oh and Kang, 2013](#)).

Flood and Waste Management Process

Management of the flood risk and waste system requires further consideration of the linkages between the tasks and components as well as their application by representatives of the society. Links between flood risk and waste analysis, flood risk and waste assessment and flood risk and waste reduction are the prerequisite for a consistent approach to steering a flood risk and waste system. Due to widely varying methods and tools incorporating these into an operation system is challenging. It should be realized

Fig. 2 Components of flood risk and waste management.

that the application of tasks and components by the representatives of the society within flood risk and waste management will normally not follow only a formal textual logic. Instead, various aspects of societal behavior influence decisions and their implementation. The usability and real usage of scientific contributions to flood risk and waste analysis, flood risk and waste assessment and flood risk and waste reduction in societal discussions and decisions are, therefore, of special importance for understanding flood risk and waste risk management.

Future Research Directions

While there are existing methodologies endeavoring to address the difficulties in incorporation and ingestion of flood risk and waste-related information, a versatile, adaptable, and adjustable arrangement that can be immediately conveyed and developed with the surge's periods hazard and waste is being looked for. Upgrades upon the functionalities and/or philosophies of the current fiasco administration frameworks, ought to be explored to guarantee a flood risk and waste planning and recuperation system that can be used under distinctive catastrophe conditions.

The information in misfortune administration application areas are gathered and put away in different media sorts, configurations, and structures from various data sources. A considerable lot of these information are gushing information and gathered progressively, which may have fleeting and spatial qualities. These information may have distinctive levels of culmination and certainty, and may be conflicting. To exacerbate things, there is likewise data shift issue in these applications. That is, the data/learning may be continually changed, obsolete, and inadequate. To our best learning, there are no current techniques and/or calculations that can legitimately address the previously stated issues acceptably. Creating novel methods for overseeing and investigating information that are from heterogeneous sources, having a blend of unstructured and organized sorts, of diverse fleeting and spatial attributes, with different wellsprings of vulnerability, is a testing errand and is critical.

Conclusions

In this paper we display surprisingly a thorough review of the endeavors on using and propelling the administration and examination of information to serve flood risk and waste administration circumstances. We sorted out our discoveries over the accompanying software engineering controls: information mix and ingestion, data extraction, data recovery, data sifting, information mining and choice backing. At long last, we displayed solid future exploration bearings for researchers to propel the information of connected information administration and investigation in surge hazard and waste administration.

Introduction

The amount of surplus food around the world is estimated at 1.3 billion tons annually. While more than 800 million hungry people exist in the world (Food and Agriculture Organization of the United Nations, 2013 (FAO)), the large amount of waste, which accounts for a large proportion of food production, contributes to many environmental, health, and social issues (Parfitt *et al.*, 2010). To reduce the issue of disposal of surplus food to landfill, its reuse must be exploited. Exploiting waste can be achieved by educating consumers about the harmful effects of food disposal; managing the waste generated by residential complexes, public places such as restaurants and hospitals would also assist in the reduction of waste accumulation in landfill. Additionally, energy plants play an important role in waste management when the waste is used in renewable energy production processes (Kibler *et al.*, 2018). The aim of this study is to demonstrate the importance of using and applying the digestate resulting from the anaerobic digestion (AD) process in a correct way and to show its negative effects on the environment when incorrectly applied.

Waste Management

The incentive for waste minimization and management has become essential, as waste accumulations lead to growing environmental hazards. This involves the recycling, reuse, or application of waste via waste generation techniques. Dealing with waste properly helps reduce greenhouse gases and thus works to reduce global warming. The UK Climate Change Act of 2008 recommended a reduction of the amount of harmful emissions by 80% by 2050 (Levidowa and Ramanb, 2019). Fig. 1 shows the EU hierarchy of waste disposal priorities by reducing, reusing, recycling, or utilizing them in energy production and finally disposal (which is the least favored option) (European Commission, 2008).

A waste management system is an integrated waste management process that begins with waste handling and ends with recycling or destruction. The waste management process goes through several steps as represented in Table 1 (Demirbas, 2011). Failure to exploit and properly utilize waste leads to loss of a source of energy in addition to the other damages caused by its accumulation (Milke, 2008).

Anaerobic Digestion

AD is an efficient and reliable method process to produce energy from natural sources. The AD process is the process of converting organic matter into biogas in the absence of oxygen through different types of bacteria. Biogas contains

Fig. 1 Waste hierarchy. Reproduced from European Commission, 2008. Directive 2008/98/EC of the European Parliament and of the Council of 19 November 2008 on waste and repealing certain Directives.

Final disposition	Recycling Landfilling

different gases in different rates. Methane is the main component of biogas generally reaching up to 60%–70%. The remaining gases contain up to 45% carbon dioxide (CO₂) and the balance includes hydrogen sulfide (Milledge and Patricia, 2018; Vanegas and Bartlett, 2013). Several types of inoculum, such as sludge from wastewater treatment plants and sludge of manures, are used in the AD process. The process of producing biogas through AD goes through four stages as described in Fig. 2 (Monlau *et al.*, 2014). There are many factors that influence the AD process, for example, the temperature effect in the thermophilic (50–60°C) condition is different than its effect in mesophilic condition (30–40°C) (Samaras *et al.*, 2012). The result of a fast reaction rate in thermophilic conditions results in a biogas that is higher than in mesophilic conditions with the potential for acidification, which affects the AD production. The rise in temperature leads to an increase in the energy used, thus raising the production cost. Mesophilic conditions are less sensitive to environmental changes and have better stability; however, the methane yield is lower than that in thermophilic conditions (Mao *et al.*, 2015; Bowen *et al.*, 2014).

Moreover, the pH, C/N ratio, retention time, and the organic load rate also have an effect on the AD process and thus affect the quantity and quality of the process output (Mao *et al.*, 2015). The bacteria growth process is affected by the pH, so the optimal value of the pH is 6.8–7.4 (Fang and Liu, 2002). Adjusting the C/N ratio to 20–25 contributes to the improvement of the AD production (Yen and Brune, 2007). The time required to keep the organic material in the reactor to complete the biogas production process is known as the retention time. The retention time depends on the temperature used and is associated with the organic load rate. The time required for completing the degradation process and producing the biogas within a mesophilic condition is 15–30 days while it is a little shorter within a thermophilic condition (Kwietniewska and Tys, 2014).

In addition to biogas, a rich nutrient digestate can be produced from an AD process. Fig. 3 shows an overview of the resulting products and their use (Møller *et al.*, 2009). Exploitation of this digestate leads to an enhanced benefit in using the AD process, by increasing the process products. The resulting digestate can be used in many fields such as a biofertilizer in agriculture. In addition to that the resulting digestate can be recirculated to reuse it in a two-stage AD process (Lia *et al.*, 2019; Wua *et al.*, 2018).

Digestate

The digestate consists of the residues of the AD process. The digestate can be used for several applications rather than just disposal (Akilaa *et al.*, 2019). The digestate is generally composed of dead microorganisms and indigestible feedstock. The rise in the price of compost makes the use of digestate as a biofertilizer more desirable (Mouat *et al.*, 2010). Nitrogen (N), phosphorus (P), and potassium (K) that exist in the feedstock reside in digestate; this presence is essential when used in agriculture (Digestate, 2019). Digestate contains carbon, which ends up being stored in the soil, thus preserving the environment from global warming (Møller *et al.*, 2009). The use of inorganic fertilizers with pesticides may lead to soil and agricultural crop damage in the future (Uthirapandi *et al.*, 2018). Biofertilizers are more favored than chemical fertilizers as they help in improving the soil and thus increase soil retention. This leads to reduced water consumption used during an irrigation process. Moreover, the need to use pesticides with biofertilizer is less than that with chemicals, leading to improved soil. The digestate represents a significant percentage of the AD residues (Møller *et al.*, 2009).

Since the soil quality is determined based on its organic material content, according to the European Commission for Standardization (AFNOR: FD CR 13456, 2001), therefore any material that modifies the soil properties can be considered as soil amendment (Nkoa, 2014; Thornton and McManus, 1994). Some digestates have shown high nitrogen levels of more than 60%, which is preferred when applied as a biofertilizer (Tambone *et al.*, 2010). Whereas for digestates where the proportion of nitrogen is around 36%, use as a soil amendment is recommended (Teglia *et al.*, 2011).

Fig. 2 Anaerobic digestion stages. Reproduced from Monlau, F., Sambusiti, C. Barakat, A., *et al.*, 2014. Do furanic and phenolic compounds of lignocellulosic and algae biomass hydrolyzate inhibit anaerobic mixed cultures? A comprehensive review. *Biotechnology Advances* 32, 934–951.

Digestate Uses

Organic fertilizer is widely used in agriculture as soil fertilizer and soil amendment. It is also used in some nonagricultural areas such as animal litter (straw). The use of digestate is mostly based on its component properties as well as the method of treatment.

In agriculture

The exploitation of huge quantities of digestate resulting from an AD process in agriculture faces challenges as an acceptable process by farmers and consumers. This is due to a lack of awareness of this type of digestate as a fertilizer and its benefits to the environment (Dahlina *et al.*, 2015). Prior to employment, the digestate produced in the agricultural field requires further treatment. In European countries, approximately 95% of the digestate produced by AD is used as an organic fertilizer substitute for chemical fertilizer in the agricultural field (Saveyn and Eder, 2013). In terms of organic products, farmers prefer organic fertilizer that complies with controlled specifications, rather than the chemical fertilizers. It also relies on biofertilizer as animal litter (straw). Some horticulture workers and home gardeners are selective in the type of fertilizer they use and rely on organic fertilizer to decorate/maintain their gardens (Dahlina *et al.*, 2015). The majority of the digestate produced by AD plants in the UK are used as a biofertilizer, while the excess quantity is disposed (Mouat *et al.*, 2010).

Recirculated in two phase anaerobic digestion

Some studies have been interested in recirculating the digestate in the AD process to produce biogases. This process has contributed by improving the biogas production yield, reducing operational costs, and reducing digestion treatment process. The recirculation process does not affect the pH of the digestate; rather it reduces its alkalinity (Wua *et al.*, 2018; Cavinato *et al.*, 2011).

Fig. 3 Anaerobic digestion products and uses. Reproduced from Møller, J., Boldrin, A., Christensen, T.H., 2009. Anaerobic digestion and digestate use: Accounting of greenhouse gases and global warming contribution. *Waste Management and Research* 27, 813–824.

Future uses

There are some areas where digestate can be applied, which may increase its reliability for consumers. It can be used in football or sports grounds. In addition, it has the potential to be expanded as a soil conditioner in private and public gardens. Biofertilizer may also be targeted towards forestry and sold at agricultural retail stores (Mouat *et al.*, 2010).

Digestate Forms

The digestate produced from the AD process can be used in the agricultural field either as whole digestate, liquid form, or solid form as shown in Figs. 4 and 5 (Nkoa, 2014; WRAP, 2012). The whole digestate is the residue of the AD process, in which the dry content ratio is less than 5%. Liquid digestate is the isolation of solids from the whole digestate. Solid digestate is known as “fiber,” and it is similar to compost, which is a solid substance isolated from liquid digestion (WRAP, 2012). Depending on the dry matter (DM) content, the digestate can be divided into three forms. The first form is dewatered where the amount of DM may reach to 35%. The second form is alkaline; where the DM ratio is up to 60%. The third form, which is fairly solid, has a DM content of up to 92% (Department of Environment and Local Government, 2013).

The presence of nitrogen and carbon in the digestate plays a major role in the possibility of using it in agriculture (Nkoa, 2014; Thornton and McManus, 1994). The digestate that is produced from food waste contains organic matter; therefore it can be used directly in the agriculture field as a soil amendment or organic fertilizer. In addition, it is also possible to separate the fibers from the liquid and use them separately. Liquid digestate can be used as an organic fertilizer, while solid digestate may be used as a soil amendment or in landscaping (Mouat *et al.*, 2010). A digestate containing a high percentage of carbon and nitrogen is preferred to be used as a biofertilizer (Tambone *et al.*, 2010). In contrast, digestate with low carbon and nitrogen content can be used as a soil amendment (Teglia *et al.*, 2011), whereas the use of liquid digestate in soil treatment increases the probability of microbes existing in the digestate and oxidation of ammonia (Nkoa, 2014).

Digestate as a Biofertilizer

The use of digestate, which contains the necessary nutrients as organic fertilizer, has a clear value. N is available in biofertilizer at high rates, especially if it is not lost during the AD process, but less than that found in compost. The availability of P and K is similar to that found in compost. Compared with compost, the use of digestate, which contains a high percentage of N as a biofertilizer, leads to increase their value in the short term (Bonten *et al.*, 2014). Fertilization of soil by composting with the participation of biofertilizer contributes to the organic balance of the soil. The presence of organic matter in the soil works to provide nutrients in the soil, which keeps its fertility (Palm *et al.*, 2001). The addition of biofertilizer to compost in soil helps in keeping the organic matter balance within the soil (Miller and Wali, 1995). In addition to that, using the digestate as organic fertilizer instead of disposal helps to reduce waste accumulation (Tambone *et al.*, 2007).

Fig. 4 Images showing three states. Reproduced from WRAP, 2012. Quality digestate: Using quality anaerobic digestate to benefit crops. 3/4/2019. Available from: <http://www.wrap.org.uk/sites/files/wrap/Usingqualitydigestatetobenefitcrops.pdf>.

Fig. 5 Anaerobic digestion solid and liquid digestate. Reproduced from Nkoa, R., 2014. Agricultural benefits and environmental risks of soil fertilization with anaerobic digestates: A review. *Agronomy for Sustainable Development* 34, 473–492.

The contribution of the AD process in the reduction of emissions is not only associated to the production of biogases. Maintaining the carbon in the soil for use as natural fertilizer is another factor in reducing harmful emissions (Møller *et al.*, 2009). **Table 2** shows the difference in digestate values from organic and inorganic feedstocks produced from the AD process.

Digestate Quality

The quality of digestate depends on three main factors. The first of these factors is the quality of the chemical product, where it is intended to contain the digestate on the three essential elements: N, P, and K. The quantity of minerals should be balanced and should not contain heavy metals and salts at high rates. Obtaining a certificate of specifications conformity contributes to greater consumer confidence. The second factor is the absence of pathogens through hygiene and heat treatment. The third quality factor is the purification of digestate from inorganic and nonbiodegradable materials such as glass, plastic, and stone, as the presence of these substances reduces the efficiency of biofertilizer and the consumer confidence. Adding some substances and structural materials to the digestate works on improving the digestate's unpleasant smell and removing dust. Digestate with high DM content makes it more likely to last longer, whereas in contrast, a fully dry digestate is not recommended as it can be exposed to wind erosion (Dahlina *et al.*, 2015).

Table 2 Digestate values based on feedstock type

Organic material	N content	Dry matter (DM) %	C/N	Fertilizer value %
Legume coarse meal	40–60 kg t ⁻¹	95	10–13	35–45
Horn/feather/leather meal	130 kg t ⁻¹	95	3–4	50–70
Brewery/distillery residues	3 kg m ⁻³	6	8–10	30–35
Meat/blood/bone meal	75–120 kg t ⁻¹	95	3–5	60–80
Green manure	10–35 kg t ⁻¹	100	10–30	10–40
Biocompost	6 kg m ⁻³	60	13–20	0–20
Solid manure	6 kg m ⁻³	25	12–15	10–20
Sewage sludge (high DM)	4–5 kg t ⁻¹	25	6–8	15–30
Dried poultry excrement	30 kg t ⁻¹	55	5	60–70
Sewage sludge (low DM)	1–2 kg m ⁻³	5	3–5	45–55
Cattle slurry	4 kg m ⁻³	7.5	8	35–45
Digestate from plant biomass	2–3 kg m ⁻³	8	5–8	40–60
Digestate with cofermentation	3–15 kg m ⁻³	5	2–5	50–70
Poultry slurry	10 kg m ⁻³	15	4	70–85
Urine	4 kg m ⁻³	2	1–2	90–100

Note: Nkoa, R., 2014. Agricultural benefits and environmental risks of soil fertilization with anaerobic digestates: A review. *Agronomy for Sustainable Development* 34, 473–492.

Constraints of Digestate Uses

There are a number of barriers that limit the use of digestate in agriculture. Digestate has no market value, so it is distributed free of charge to farmers. The small percentage of DM makes the digestate transportation process costly. Further treatment of the digestate is necessary to reduce the DM (Mouat *et al.*, 2010). Concentrating on the biogas yield produced by the AD process, without taking into account the digestate produced efficiency, can result in the producing unsuitable digestate. For example, the reduction of the retention time or temperature in the AD process to reduce the production cost may lead to the emission of unpleasant odors from the digestate or containing toxic organic compounds (Nkoa, 2014).

There is a possibility that greenhouse gases can be released from the digestate when stored or used in agriculture as fertilizer or soil amendment. Improper storage and use of the digestate causes an emission of nitrogen or nitrous oxide from it (Nkoa, 2014). Combining methane and CO₂ in biogas resulting from the AD process leads to an increase the amount of nitrogen present in the digestate and thus decreases the C/N ratio (Möller and Stinner, 2009). Temperature and pH play a significant role in the determination of the C/N ratio and subsequently the gaseous emissions. Furthermore, factors such as humidity, ammonia concentration, and wind speed have an effect on gaseous emissions (Holm-Nielsen *et al.*, 2009). 80% of the ammonia emitted from the soils fed by the digestate remains in the air and the rest returns to the ground in an area of about one kilometer (Nkoa, 2014). These high levels of ammonia in the air have led to the formation of fog in the air, which limits the level of visibility. Small and volatile ammonia atoms may penetrate the human body causing respiratory health problems (EPA, 2004).

Nitrous oxide has a strong and harmful effect on global warming, often hundreds of times more than the effect of CO₂ (Ravishankara *et al.*, 2009). Emissions from soil account for about 50% of total emissions and the same proportion represents agricultural emissions from the soil emissions (Denman *et al.*, 2007). More than 70% of nitrous oxide emissions are from agricultural applications (Lemke *et al.*, 1998). Emissions of ammonia increase with digested fertilizer compared with undigested, while nitrous oxide is reduced with the digestion process. This may be due to the low carbon ratio that has been converted into biogas (Vallejo *et al.*, 2006). The decrease in nitrous oxide emissions may reach more than 60% with digested fertilizer (Chantigny *et al.*, 2007). Proper use of biofertilizer produced from the AD process, which helps in aeration and good drainage of soil, helps to reduce nitrous oxide emissions (Nkoa, 2014).

On the other hand, pollution is also a concern generated due to the presence of nutrient contents in high ratios on the surface water and ground water. The amount of mineral in biofertilizer is higher to what is found in compost (Haraldsen *et al.*, 2011). The association of compost with environmental issues is likely to increase with applying biofertilizer, especially if precautions are not taken to prevent this when using and producing the AD digestate (Mulla *et al.*, 2001). Caution also extends to the possibility of contaminants, such as physical (plastic or glass), chemical (toxic compounds, heavy metals), and biological (bacteria) (Nkoa, 2014).

Digestate Treatment

Difficulties facing the use of digestate, such as the difficulty of transportation, storage, and its direct use in some cases, lead to the reason to investigate the benefits of the treatment process. There are some other methods of treatment, but to choose the favorite one is complex, as the consumer desires various characteristics of the biofertilizer produced. The determination of the method of treatment depends on the digestate formed (liquid or solid). Moreover, the costs of the treatment methods have a role in determining the ideal method (Mouat *et al.*, 2010). If the liquid digestate contains less than 5% DM (WRAP, 2012), it is easy to spread onto the soil and use directly as a biofertilizer. The dry digestate can be used directly as a soil amendment or be treated and used as a biofertilizer (Rapport *et al.*, 2008).

Dewatering of the digestate is a process of removing water from the digestate to obtain the liquid and solid digestate separately. Distilled water can be used for irrigation, due to its acceptable quality, which contributes in the reduction of water use. This process reduces the transportation costs and the ease of storage. The dewatering process can be carried out in several ways. *Gravity tables*: The costs of this process are low as they depend on the costs of establishment. Based on the feedstock, this process may reduce water content by 15%. *Press*: This technique does not require a lot of energy. Press is currently applied in small and medium-sized factories. *Drying*: This is drying the digestate by heat evaporation. Drying controls the desired dryness degree of digestate. The drying equipment is the main cost of the process, but the process produces less water combined with the digestate. It cleans the digestate from impurities and health hazards. *Rolling*: The solids are separated from water instead of removing water from digestate. Small particles accumulate around the tank wall during a rolling process and then are converted into pellets, which can be easily removed from the liquid (Mouat *et al.*, 2010).

Liquid and solid digestate can be mixed with enhancing materials to attain better results. Liquid digestate can be mixed with sawdust to add longer consumption periods. It is possible to mix solid digestate with nutrients to enhance it; these may be used in gardens and horticulture. It also facilitates the transportation process and allows for longer storage (Mouat *et al.*, 2010).

Further Studies

Further studies are required with respect to the digestion resulting from waste treatment, especially from AD. Some of the topics that need to be investigated have already been specified in this article. The relationship between the feedstocks and the digestate require more clarity, especially with respect to the proportions and properties of organic substances in the digestate. Furthermore, the long-term effects of using the digestate in agricultural soils on soil properties need to be further studied. Some types of digestate may contain bacteria and fungal pathogens and thus need to be identified and controlled. There is also a need to study the harmful emissions from the digestate such as the emissions of ammonia and nitrous oxide, which adversely affect the environment and the efficiency of digestate (Nkoa, 2014).

Conclusion

Waste management in general and food waste in particular contribute to reducing the environmental and health effects of the accumulation of waste. This is done by raising the awareness of the community and society about the importance of waste recycling or its use in different fields. AD is one of the technologies used broadly, which is proven to be effective in converting waste into biogas and digestate.

The low proportion of DM in the digestate makes storage difficult and transportation to far destinations impossible. The shortage of sources for the emissions of the digestate and its impacts on the environment are an impediment to its application. Despite that the application of digestate as a biofertilizer in agriculture can cause damage to the plants and others, it could help in mitigating the obstacles threatening the sustainability of the AD, if it is properly handled. However, more investigations are required for increasing the awareness of farmers and others on the digestate, thus, increasing the reliance on and use of it.

However, the digestate is a promising alternative to chemical fertilizers if treated appropriately, especially with the rise in the price of compost compared with biofertilizer. Moreover, its exploitation by AD plants may enhance the feasibility of the process and reduce its operational costs.

Experimental Investigation of Microtest Specimens of Renewable Material-Based Composite Materials by Injection Molding

H Chin How and M Azuddin, University of Malaya, Kuala Lumpur, Malaysia

Introduction

Plastic Injection Molding

Plastic products can be found everywhere. These plastic products have many advantages, including their lightweight, high stiffness, ease of production, ability to be produced in high quantities, and high quality (Kitayama and Natsume, 2014). Injection molding is the most common processing technique used in the plastic industry. It can be used to process several types of materials and to produce products with complex geometries. However, some defects exist in plastic injection molding, such as warpage, volume shrinkage, weld lines, and short shots. The plastic injection molding process can be divided into four phases: filling, packing, cooling, and ejecting (Kitayama and Natsume, 2014; Gerber *et al.*, 2006).

The processing parameters of plastic injection molding are nonlinear and interacting. Control of the melt temperature for injection molding is very important. It can be considered to be the most critical factor in injection molding because it directly influences the viscosity of the melt. Having good control of the melt temperature is also important for reducing the setup time, assuring consistent product quality, and preventing the melt from being thermally degraded. The melt temperature and melt viscosity can influence the velocity of the translational injection, the speed of the rotational reciprocating screw, and the cavity pressure–time profile (Dubay, 2002). In this study, a rotating twin screw extruder was used to investigate the processing parameters of kenaf fiber composites at two different temperatures, low processing temperature (LPT) and high processing temperature (HPT). The tensile modulus increased with the increase in the compounding temperature and fiber loading when processed at LPT and HPT. Conversely, by increasing the content of the fiber, the tensile strength of the composites decreased at both LPT and HPT. However, the composites processed at HPT presented better tensile strength than those at LPT. The tensile strains of the composites decreased with increasing fiber loading, whereas composites processed at LPT showed higher tensile strain than those at HPT. In summary, the composites processed at HPT showed the best performance of tensile properties (Salleh *et al.*, 2014).

Huang (2007) stated that the process control parameters for injection molding are a complex problem. The melt temperature is a very important process parameter for all phases of the cycle of injection molding, such as filling, packing, holding, and cooling. Control of the melt parameter is difficult due to nonlinear polymeric melting processes. Because the melting of plastic is an endothermic process, and because the situation is further complicated by the poor conductivity of plastics, it is difficult to control the melt temperature. Due to the viscosity dependence on temperature, the melt temperature will influence some other parameters, including the rate of melt flow, the nozzle pressure, and the cavity pressure–time profile. As a result, the melt temperature will affect the final quality of the molded part. Holding happens once the cavity is filled. Then, holding pressure will be maintained, while the additional plastic melt is packed into the cavity to compensate for the plastic shrinkage caused by cooling. Packing–holding pressure will affect the injection molding quality. Different types of packing profiles will affect the part weight, shrinkage, flash, thickness distribution, and evenness (Bobzin *et al.*, 2011). Processing parameters, such as holding pressure and mold temperature, were investigated in this study for their effects on residual stresses in the molded parts (Murakami *et al.*, 2007).

Micro Plastic Injection Molding

Microinjection molding is a process that transfers a granule form of thermoplastic from the hopper into a heated barrel to heat the thermoplastic into a molten state. Then, using pressure, the thermoplastic is pushed inside a mold cavity where it is subjected to holding pressure for a certain amount of time to prevent the thermoplastic from shrinking. As the temperature of the mold decreases, the thermoplastic inside the mold cavity solidifies. Then, the part is ejected and the cycle is repeated (Attia *et al.*, 2009). The main elements that influence the quality of the part produced by microinjection molding are the temperatures of melt and mold and injection speed. If the temperature of the mold increases, then the cycle time also increases. As a result, this will cause a reduction in the process output and in the costs of the parts. However, high melt and mold temperatures and high injection speeds will provide a good influence on the melt flow in tiny cavities (Sha *et al.*, 2007). Microinjection molding requires special conditions that will affect the chemical, physical, and thermal properties of the injected polymeric material. The material behavior is different from that during the classical process of injection molding. Hence, the parameters of the injection process need to be optimized (Gheorghe *et al.*, 2014). Zhao *et al.* (2003) stated that a microsystem has been given considerable interest in recent years. It is expected to extend toward miniaturization of components and to be increasingly applied for micro-sized devices. The microinjection molding process of polymers is the key to enabling the microsystem to be capable of mass production of microcomponents at a low cost. Polymers play an important role in the growth of microsystem applications because they are available in various compositions, properties, and forms and can be fabricated into complex structures. The demand for increasingly smaller molded plastic components has increased because of the trend toward miniaturization. Yao and Kim (2002)

stated that there are many advantages to further development of microinjection molding. The advantages comprise the vast variety of plastics available and the possibility of fully automated operation with short cycle times, cost-effectiveness for mass production, high accuracy of shape replication, good dimension control, and low maintenance costs of the capital equipment. Microinjection molding is crucial for micro-manufacturing because it is capable of producing large amounts of standardized products with low component costs. With the development of micro-engineering technologies, product miniaturization has increased (Sha *et al.*, 2007). It is not surprising that miniaturized parts exist in many places in our daily lives (Piotter *et al.*, 2002). Kukla *et al.* (1998) defined the meaning of microinjection molding. First, the weight of the microinjection-molded part is just a few milligrams. The part does not need to have dimensions with a scale of micrometer. Second, an injection-molded part with micro-structured regions is usually a part on a conventional scale that is characterized by dimensions in the micrometer range. Third, a micro-precision part can have any dimensions but has tolerances in the micrometer range.

Microinjection Molding Machine

Injection machines have been challenged to produce micro-features. This is because of the processing requirements to fill the cavities of the mold completely in the micro-range before solidification of the material starts. This challenge existed before the spread of microinjection molding, when the same problem was encountered by thin-wall injection molding. This problem can be solved by changing some processing parameters in conventional injection machines, such as the injection speed and pressure. To solve the problems of producing parts with micro-features, injection machines need to be modified to produce the parts. Some modifications include smaller plasticization units, clamping units with lower tonnage, advanced control systems with accurate parameter control, temperature variation programs, air evacuation systems, and handling and inspection. Many manufacturers are beginning to show an interest in producing microinjection molding machines (Attia *et al.*, 2009).

Natural Fiber Composite

A fiber-reinforced polymer is a composite material comprising a polymer matrix embedded with fibers with higher strength. Polymers can be divided into two types, thermoplastics and thermosetting. Normally, thermoplastics are used as matrices for natural fibers. Malkapuram *et al.* (2008) and Groover *et al.* (2004) presented that polypropylene (PP), poly vinyl chloride (PVC), and polyethylene (PE) are the most common thermoplastics used for fiber-reinforced polymers. Natural fiber composites are becoming more and more popular. This is because natural fibers are lightweight, nontoxic, low cost, and biodegradable. Moreover, the use of natural fibers is positive for the environment because of their disposability and raw material utilization (Narayan, 1992). Natural fibers are made from animal, plant, and mineral sources. A plant fiber is a very important part of natural fibers, which include fibers from bast, leaf, seed, fruit, wood, cereal straw, and grass. Over the past few years, natural fibers have become an attractive alternative to synthetic fibers. This is because of the advantages of natural fibers, such as low density, less damage to the machine, recyclability, renewability, and good mechanical properties. Natural fibers can be used to replace the existing glass fiber-reinforced polymer composites because their strength is comparable to that of glass fibers (Hojo *et al.*, 2014).

Scientists and technologists have been attracted to natural fibers because of their various applications. Natural fibers have good thermal and insulating properties, better electrical resistance, higher resistance to fracture, and are renewable. Natural fibers do not cause skin irritations and possess relatively high strength and stiffness. However, natural fibers do have disadvantages, such as low thermal stability, moisture uptake, and quality variations. Many studies have investigated the properties of natural fiber composites. The results have shown similar outcomes indicating that natural fiber composites possess good stiffness but have lower strength levels than glass fiber composites (Oksman, 2001). There are several elements that can affect the properties of natural fiber composites. The properties of the natural fiber composites can be affected by the content of fiber or amount of filler and the hydrophilic nature of the fiber. To achieve high performance of the composites, the fiber content needs to be high. The fiber content has a significant influence on the performance of natural fiber composites. The increase in fiber loading can cause an increase in the tensile properties (Arib *et al.*, 2006). Furthermore, the processing parameters are very important because they significantly affect the performance of the natural fiber composites (Ku *et al.*, 2011). Sathishkumar *et al.* (2012) stated that several authors have researched natural fibers due to the demand to create natural fiber composites. Athijayamani *et al.* (2009) used the fibers of roselle and sisal to compare their experimental tensile and flexural strength using the Hirsch theoretical model. Bakare *et al.* (2010) investigated the mechanical properties of the sisal fiber composite under two conditions, with and without the water treatment process. Cao and Wu (2008) found out that the optimum strength of the bamboo fiber is higher than that of other fiber-reinforced green composites. Gonzalez-Murillo and Ansell (2009) proposed that the results of chemically treated fiber composites and untreated fiber composites are similar. Silva *et al.* (2008) studied the tensile properties of the sisal fiber. Joseph *et al.* (1999) studied and compared the tensile strength and modulus of natural fiber composites.

PP-Based Composites

Composites of bast fibers, which are an annual fiber crop, with PP provide materials with interesting price or performance ratios. These composites are suitable for making interior parts for cars. Their fiber and matrix properties can be improved with modified PP, which increases compatibility (Bos *et al.*, 2002). Many materials have been used as reinforcing agents to improve the

mechanical properties of PP. Asbestos tailings were recycled and chemically modified to increase the compatibility with the PP matrix (Zhai *et al.*, 2014). Olive stone flour extracted from the solid residue of olive oil has been used to reinforce the PP. These materials are definitely creating new perspectives regarding the functions of industry by-products (Naghmouchi *et al.*, 2015).

Kenaf fibers

Kenaf fiber is a natural and environmentally friendly fiber used to produce natural fiber composites. There are several methods of producing natural fiber composites, such as extrusion, compression, and injection molding (Salleh *et al.*, 2014). Nishino *et al.* (2003) performed an investigation regarding the fiber content and mechanical properties of kenaf fiber composites. In their investigation, Young's modulus and tensile strength increased with an increase in fiber content. Kenaf fiber is a high performance biodegradable polymer composite. It does not cause environmental problems when disposed of like conventional and traditional fiber-reinforced composites do.

Rice husk fibers

Rice husk is the outer layer of rice grains. It is an agricultural by-product. Rice husk ash results from burning the rice husk and contains a high amount of silica. Rice husk ash can be a supplementary material used to replace Portland cement. Rice husk ash can act as a reinforcing agent in the making of cement; it can reinforce the strength of cement. A high level of fineness of rice husk ash can enhance the compressive strength of cement (Hamzeh *et al.*, 2013). As an agricultural by-product, rice husk is useful and has been applied for bio-fertilizers, animal husbandry materials, absorbent materials, and pest control agents. Due to its abundance, composition, and low cost, several studies have investigated the possible functions of rice husk. However, rice husk has not yet been included in bio-based composites used in melt blending (Battezzore *et al.*, 2014).

Flax fibers

Mechanical properties of flax fibers, such as tension and compression have been studied. The clamping length can greatly affect the tensile strength of technical fiber bundles. The compressive strength of elementary flax fibers can be reduced by the decortication process. The failure behavior of elementary flax fibers under compression is similar to that of a stranded wire. It was presented that flax is one fiber that possesses the best mechanical properties (Bos *et al.*, 2002).

Coconut shell fibers

Coconut shell, which is an agricultural by-product, is the waste product of food processing that possesses sufficient value regarding fibers. It is a cheap engineering material that can help to reduce waste (Bledzki *et al.*, 2010). The potential of grain by-products, such as soft wood and coconut shell, as the reinforcements for thermoplastic was investigated in this study. The thermal degradation characteristics of coconut shell fibers were studied for their potential to be processed as reinforcements for PP.

Numerical Studies

ABAQUS, a finite element software, was used in implementation of the extended finite element method (X-FEM), a powerful numerical procedure for the analysis of crack problems. The crack growth modeling capabilities of X-FEM can be beneficial for those familiar with ABAQUS (Giner *et al.*, 2009). The capabilities of ABAQUS to extend the finite element code were presented to simulate the history of heat treatment phase transformations and distributions of residual stress. Simulation is a tool that is inexpensive, secure, and time-saving (Yaakoubi *et al.*, 2013). Shallow, thin-walled parts of wood polymer composites were produced by injection molding. The parts were investigated by conducting a simulation with Autodesk MoldFlow Insight software. The simulation was performed by using a set analysis of "Fill + Cool + Fill + Pack + Warp" (Azaman *et al.*, 2014).

Summary

Injection molding is widely used in the plastic industry to produce parts. Because the market now prefers products that are small, light, and slim, the parts produced need to be as small as possible. The industry also started noticing the importance of microinjection molding and how profitable it could be. The processing parameters and materials used for injection molding were studied to improve the process. Due to the increasing awareness of the public regarding environmental conservation, environmentally friendly materials are more likely to become the materials of choice. Natural fiber composites are environmentally friendly because they are made from natural fibers. Therefore, many experiments have been performed to study the mechanical properties of the natural fiber composites. It has been discovered that studies regarding the effects of processing parameters of injection molding on the mechanical properties of specimens made from different types of PP-based natural fiber composites are limited. Hence, this study was conducted to investigate the effects and to provide more information regarding the future utilization of PP-based natural fiber composites. Microtensile specimens will be prepared by injection molding with different types of natural fiber composites and combinations of processing parameters. Specimens will be tested and the experimental results will be compared with the finite element analysis (FEA) obtained from ABAQUS.

Fig. 1 Vertical injection molding machine.

Methodology

In this study, three phases were performed to investigate the mechanical properties of the natural fiber composites.

1. Injection molding: microtensile test specimens with different types of natural fiber composites and processing parameters need to be prepared by injection molding. The microtensile test specimens are prepared by using the D1708-02a standard.
2. Microtensile test: the microtensile test specimens are tested by following the standard D638. The mechanical properties of different specimens will be studied. Then, data collection and analysis are performed.
3. ABAQUS tensile test simulation: simulation of the tensile test for the specimens will be performed by using the data collected during microtensile testing via FEA software (ABAQUS). The experimental results will be compared with the results obtained by ABAQUS.

Injection Molding Apparatus

The test specimens used in this study were produced by a vertical injection molding machine (**Fig. 1**; *Azuddin et al., 2015*). The original unit used a pneumatic system to generate the plunger injection motion. However, injection molding of natural fiber composites requires higher pressure than thermoplastics because of their higher viscosity. Hence, the injection molding machine was modified and the pneumatic unit was replaced by a hydraulic unit due to insufficient pressure. The hydraulic pump can provide higher pressure to the injection plunger to deliver melted natural fiber composites into the mold cavity. The machine also includes a temperature controller to control various melt temperature.

Mold for Microtensile Specimen

The mold cavity was fixed and the dimensions of the test specimen were used following the standard of the microtensile specimen, D1708-02a (standard test method for tensile properties of plastics by use of microtensile specimens) (**Fig. 2(a)**). **Fig. 2(b)** shows the mold used to produce the microtensile specimen.

Materials

For composites preparation, fibers were mixed with PP in a mixer using standard compounding operations. Fibers were responsible for 30 wt% of the composition. The fiber was compounded on a twin screw extruder. At the end of the extruder, the melt goes through a die plate and into a water bath. Finally, a cutter is used. Three types of natural fiber composites (from RheTech, Inc., United States) were used in this study:

Fig. 2 (a) Dimensions of the microtensile specimen in millimeter and (b) the mold.

Fig. 3 Fiber material used in the experiment: (a) rice husk, (b) flax, and (c) coconut shell.

1. 30% Rice husk fiber-reinforced PP copolymer.
2. 30% Flax fiber-reinforced pp copolymer.
3. 30% Coconut shell fiber-reinforced PP copolymer.

A unique characteristic of the rice husk is that it is naturally flame-resistant. Rice husk is stiff, dimensionally stable, has low moisture absorption, has lower specific gravity than minerals, has excellent chemical resistance, and is naturally flame-resistant. **Fig. 3(a)** shows raw rice husk material. Flax is grown for flax seed, oil, and fiber. Flax fiber-reinforced material (**Fig. 3(b)**) are dimensionally stable, have low moisture absorption, and have excellent chemical and mold resistance. It is suitable for glass fiber replacement. Coconuts are a staple product grown around the world and have multiple uses. Both fine and coarse ground coconut shells are utilized to produce PP compounds (**Fig. 3(c)**). Coconut shell-reinforced materials have good surface hardness, stiffness, low moisture absorption, and are suitable for mineral replacement. All natural fiber PP composites used for this study were from RheTech. **Fig. 4** shows the raw fiber material and microtensile specimen after being molded.

Processing parameters

Only two processing parameters were varied in this study:

1. Melt temperature, which can be controlled by adjusting the temperature of the heater. The melt temperatures used were 230, 240, and 250°C.
2. Holding time, which can be controlled by holding the pressure of the hydraulic pump. The holding times used were 3 and 5 s.

Tensile Test

The ISO standard D1708-02a microtensile specimen was used to perform the test for tensile properties of the natural fiber composites. This test method was superseded for general use by Test Method ASTM D638, which is the test method for tensile properties of plastics. The Instron 5569 mechanical testing system was used to conduct the tensile test. Five test specimens were tested for each natural fiber composite and processing parameter. Results obtained for test specimens that broke because of some obvious fortuitous flaw or at the edge of the grips were discarded and retests were performed. Testing was the velocity of the separation of the two grips of the testing machine when it was not under any load. The speed of testing used for this project was

Fig. 4 Fiber material used in the experiment, raw pallet, and microtensile specimen after injection molding: (a) rice husk, (b) flax, and (c) coconut shell.

1.0 mm/min. **Fig. 5** shows the microtensile specimen before and after testing. It clearly shows the location of failure after the tensile test was conducted.

Tensile Test Simulation

In this study, ABAQUS CAE was used for the modeling and analysis of mechanical components and assemblies and for visualizing the result of FEA. The tensile properties of the test specimens made from different types of natural fiber composites and different combinations of processing parameters were simulated using ABAQUS. The analysis types used for ABAQUS simulations were 3D, deformable solid, and dynamic explicit. The dynamic explicit FEM analysis uses an incremental procedure. At the end of each increment, the stiffness of matrix based on geometry changes is updated. Then, a new stiffness matrix is constructed and the next increment of displacement is applied to the system. Therefore, more accurate results can be achieved. The steps begin with microtensile geometry construction according to the standard. After meshing the part geometry with the element type in this study, the types of elements used were the 4-node bilinear axisymmetric quadrilateral (CAX4R) and the 3-node linear axisymmetric triangle (CAX3). The total number of nodes was 493 and number of elements for the microtensile geometry was 428. Next, we applied the boundary conditions and minimal constraint of the bottom surface of the microtensile, and we prevented rigid body motion. A second boundary condition was created to impose vertical displacement along the top surface of the microtensile. The microtensile was loaded by imposing displacements because that results in a more gradual failure process than a similar loading using applied forces. Then, the ABAQUS simulation was performed. Finally, we viewed and interpreted the results. From these simulation results, load displacement and stress-strain results were obtained. After the simulation, results from the FEA need to be validated with the experimental result to investigate whether the results obtained from ABAQUS were theoretically accurate. **Fig. 6(a)** and **(b)** shows the composite after tensile testing and ABAQUS simulation; the microtensile specimen break locations were similar to those predicted by the ABAQUS simulation and the crack location after testing and the highest stress value (red) during the ABAQUS simulation.

Result and Discussion

Experimental Result

During injection molding, five specimens are made for each type of natural fiber composite material and combination of processing parameters. There are three types of natural fiber composite materials and six combinations of processing parameters for each material. Hence, 90 specimens are made and 18 experiments are conducted. **Table 1** shows the average of tensile strength values obtained during the tensile test for the specimens created by three types of natural fiber composite materials with different processing parameters. The flax fiber-reinforced PP copolymer had the highest tensile strength value among the three materials regardless of the combination of processing parameters, whereas the rice husk fiber-reinforced PP copolymer has the second highest value, followed by the coconut shell fiber-reinforced PP copolymer.

Table 1 Tensile strength for three different types of fiber-reinforced polypropylene (PP)

Experiment	Material	Melt temperature (°C)	Holding time (s)	Young's modulus, E (MPa) average	Tensile strength (MPa) average
1	Rice husk-reinforced PP copolymer	230	3	1512.4112	12.21
2			5	1694.676	13.208
3		240	3	1601.8112	12.008
4			5	1527.3378	11.632
5		250	3	1443.7216	10.874
6			5	1558.7406	10.804
7	Flax fiber-reinforced PP copolymer	230	3	1838.7948	14.638
8			5	2635.9876	14.958
9		240	3	2477.0482	16.032
10			5	2401.6192	15.936
11		250	3	2232.9858	16.278
12			5	2354.7464	16.514
13	Coconut shell fiber-reinforced PP copolymer	230	3	984.7912	9.54
14			5	600.4156	7.36
15		240	3	472.6668	5.458
16			5	575.1648	6.776
17		250	3	501.2308	7.374
18			5	579.8768	8.07

Young's Modulus

For the rice husk fiber-reinforced PP copolymer, **Table 1** shows that the Young's modulus increased 5.9% to 1601.8112 MPa when the holding time was 3 s, and the melt temperature increased from 230 to 240°C. However, when the melt temperature increased from 240 to 250°C, Young's modulus decreased 9.9% to 1443.7216 MPa. In addition, when the holding time was 5 s, Young's modulus for the rice husk fiber-reinforced PP copolymer decreased 9.9% to 1527.3378 MPa. The melt temperature increased from 230 to 240°C, but Young's modulus increased slightly (2.1%) to 1558.7406 MPa when the melt temperature increased 10°C more to 250°C.

Table 1 also shows Young's modulus for the flax fiber-reinforced PP copolymer of different processing parameters. When the holding time was 3 s, the value of its Young's modulus processed at the melt temperature of 230°C was 1838.7948 MPa. First, Young's modulus increased quarterly (25.8%) to 2477.0482 MPa, whereas the melt temperature increased to 240°C. Then, Young's modulus of the copolymer experienced a decrease of 9.9% to 2232.9858 MPa when the melt temperature increased from 240 to 250°C. Moreover, when the holding time was 5 s, the increase in melt temperature from 230 to 250°C resulted in decrease in Young's modulus of the flax fiber-reinforced PP copolymer (overall 10.7%). At a melt temperature of 230°C, Young's modulus was 2635.9876 MPa. It then decreased to 2401.6192 MPa at 240°C. Young's modulus continued to decrease to 2354.7464 MPa at 250°C.

Comparisons of Young's modulus for the coconut shell fiber-reinforced PP copolymer of different processing parameters are shown in **Table 1**. When the holding time was 3 s, Young's modulus for the coconut shell fiber-reinforced PP copolymer processed at the melt temperature of 230°C was 984.7912 MPa. It was then approximately halved by 52% to 472.6668 MPa for the copolymer processed at the melt temperature of 240°C. However, Young's modulus for the coconut shell fiber-reinforced PP copolymer increased marginally (5.7%) to 501.2308 MPa when the melt temperature of the copolymer increased 10°C from 240 to 250°C. Furthermore, when the holding time was 5 s, Young's modulus for the coconut shell fiber-reinforced PP copolymer remained steadily ($\pm 4.4\%$) at three different melt temperatures: 230, 240, and 250°C.

By comparing these three types of natural fiber-reinforced PP copolymers, the flax fiber-reinforced PP copolymer exhibited the highest Young's modulus value among the three copolymers; the rice husk fiber-reinforced PP copolymer had the second highest value; and the coconut shell fiber-reinforced PP copolymer had the lowest value. This indicated that the flax fiber-reinforced PP copolymer possessed the greatest stiffness among the three copolymers; the rice husk fiber-reinforced PP copolymer had the second greatest stiffness and the coconut shell fiber-reinforced PP copolymer had the lowest stiffness.

Stress–Strain Curve

The stress–strain curve is an extremely important graphical measure of a material's mechanical properties. It is unique for each material. The stress–strain curve is found by recording the amount of deformation at distinct intervals of tensile loading. The curve can be used to determine many properties of material, such as the modulus of elasticity, yield strength, and many more.

Raw data were obtained from the tensile test and curves were plotted. In **Figs. 7–9**, comparisons of stress–strain curves for each type of natural fiber composite material with different processing parameters are exhibited. The shapes of the curves for these three natural fiber composites were not exactly same, but an identical trend was shown. First, every curve started with an increasing gradient. After it increased to a certain extent, the curve remained constant and became flat. The curve rose again until the specimen

Fig. 7 Comparison of stress–strain curves for the rice husk fiber-reinforced polypropylene (PP) copolymer with different processing parameters.

Fig. 8 Comparison of stress–strain curves for the flax fiber-reinforced polypropylene (PP) copolymer with different processing parameters.

Fig. 9 Comparison of stress–strain curves for the coconut shell fiber-reinforced polypropylene (PP) copolymer with different processing parameters.

broke, and then it gradually fell. This trend of the curves for natural fiber-reinforced PP copolymers showed differences from those of neat PP, which does not undergo the constant stage in the stress–strain curve like the fiber-reinforced PP copolymer does. This constant stage in the stress–strain curve of the fiber-reinforced PP copolymer may be caused by a phenomenon called fiber pull-out. Fiber pull-out is a failure mechanism for fiber-reinforced composite materials. The cause of fiber pull-out is weak adhesive bonding between the fibers and the polymer matrix.

Effect of Melt Temperature and Holding Time

Rice husk fiber-reinforced PP copolymer

Fig. 10 shows the tensile strength for the rice husk fiber-reinforced PP copolymer with different processing parameters. The tensile strength exhibited the same trend for both holding times. The increase in melt temperature from 230 to 250°C results in an overall decrease of 10.9% in tensile strength with 3 s of holding time and 18.2% in tensile strength with 5 s of holding time. Tensile strength values reached the highest point at a melt temperature of 230°C. When the holding time was 3 s, the tensile strength value was 12.21 MPa at a melt temperature of 230°C. The value then decreased 1.7% to 12.008 MPa at 240°C. As the melt temperature continued to increase to 250°C, the tensile strength decreased 9.4% again to 10.874 MPa. Furthermore, when the holding time was 5 s, the tensile strength value was 13.208 MPa at the melt temperature of 230°C. The value then decreased 11.9% to 11.632 MPa at 240°C. As the melt temperature continued to increase to 250°C, the tensile strength decreased 7.1% again to 10.804 MPa.

Flax fiber-reinforced PP copolymer

Fig. 11 shows the tensile strength for the flax fiber-reinforced PP copolymer with different processing parameters. Both of the lines exhibited the same trend for both holding times. Overall, it increased 11.2% with 3 s of holding time and 10.4% with 5 s of holding time when the melt temperature increased from 230 to 250°C. Tensile strength values reached the highest point at the melt temperature of 250°C. When the holding time was 3 s, the tensile strength was 14.638 MPa at a melt temperature of 230°C. It

Fig. 10 Comparison of tensile strength for the rice husk fiber-reinforced polypropylene (PP) copolymer with different processing parameters.

Fig. 11 Comparisons of tensile strength for the flax fiber-reinforced polypropylene (PP) copolymer with different processing parameters.

Fig. 12 Comparisons of tensile strength for the coconut shell fiber-reinforced polypropylene (PP) copolymer with different processing parameters.

increased 9.5% to 16.032 MPa at 240°C. Then, it continued to increase 1.5% to 16.278 MPa as the melt temperature increased to 250°C. When the holding time was 5 s, the tensile strength was 14.958 MPa at a melt temperature of 230°C. It increased 6.5% to 15.936 MPa at 240°C. Then, it continued to increase 3.6% to 16.514 MPa as the melt temperature increased to 250°C.

Coconut shell fiber-reinforced PP copolymer

For both holding times, Fig. 12 shows that the tensile strength for the coconut fiber-reinforced PP copolymer displayed the same trend, with the curves decreasing when the melt temperature increased from 230 to 240°C but increasing when the melt temperature increased from 240 to 250°C. When the holding time was 3 s, the copolymer reached the highest tensile strength value at a melt temperature of 230°C (9.54 MPa). It then decreased (42.8%) to 5.45 MPa at 240°C. Nonetheless, as the melt temperature increased to 250°C, the tensile strength of the copolymer increased 35.1% to 7.374 MPa. When the holding time was 5 s, the tensile strength of the copolymer was 7.36 MPa at a melt temperature of 230°C. A slight decrease (7.9%) occurred at 240°C, resulting in a value 6.776 MPa. At a melt temperature of 250°C, the tensile strength value increased 19.1% and reached the highest point (8.07 MPa).

Figs. 10–12 show comparisons of tensile strength values for each of the three types of natural fiber-reinforced PP copolymers with different processing parameters. The trend of the tensile strength for the coconut shell fiber-reinforced PP copolymer was

inconsistent. Therefore, it can be concluded that there was no significant relationship between tensile strength and processing parameters for the coconut shell fiber-reinforced PP copolymer. Regarding the flax fiber-reinforced PP copolymer, a different observation was made. A trend can be noticed from the values of tensile strength. The tensile strength of the flax fiber-reinforced PP copolymer increased with the increase in the melt temperature. Additionally, a trend was observed for the rice husk fiber-reinforced PP copolymer. The trend indicated that the tensile strength of the rice husk fiber-reinforced PP copolymer decreased with the increase in melt temperature. By comparing these three types of natural fiber-reinforced PP copolymers, it was shown that the flax fiber-reinforced PP copolymer exhibited the highest tensile strength value among the three copolymers. This indicated that the flax fiber-reinforced PP copolymer can withstand more stress while being stretched or pulled than the other two copolymers. It could be observed that the tensile strength for all three types of natural fiber-reinforced PP copolymers used in this study was lower than that of neat PP (25–40 MPa). Although this shows that the strength of fiber-reinforced PP copolymers is weaker than that of neat PP, using fiber-reinforced PP copolymers has advantages. For example, natural fiber-reinforced PP copolymers are more environmentally friendly.

Experimental and Simulation Results

Simulations of the microtensile test for the specimens made from three natural fiber composite materials with different combinations of processing parameters were conducted by using ABAQUS software. Some data obtained from the microtensile test were inputted in ABAQUS to perform simulations. These data were Young's modulus, Poisson's ratio, yield stress, and plastic strain. Furthermore, the density of the material is also needed for the simulation. A total of 18 simulations were performed.

Fig. 13 shows an example of a comparison of the simulated stress–strain curve with the experimental curve for the coconut shell fiber-reinforced PP copolymer processed at a melt temperature of 230°C and holding time of 3 s. Two curves are displayed in the figure. The solid curve represents the ABAQUS simulation results; the dotted curve represents the results of the experiment. These two curves were plotted using the raw data obtained from the experimental tensile test and the ABAQUS simulation of the tensile test. From the graph, it can be observed that two curves have an identical shape and show an identical trend.

Rice husk fiber-reinforced PP copolymer

Comparison of the simulated stress–strain curve with the stress–strain curve obtained after the experiment for the rice husk fiber-reinforced PP copolymer at melt temperatures of 230, 240, and 250°C with a holding time of 3 s is shown in Fig. 14. There was not

Fig. 13 Example of comparison of the simulated stress–strain curve with the experimental curve (coconut shell fiber-reinforced polypropylene (PP) copolymer: melt temperature, 230°C; holding time, 3 s).

Fig. 14 Simulated and experimental stress–strain curves. Rice husk fiber-reinforced polypropylene (PP) copolymer. Melt temperatures of 230, 240, and 250°C. Holding time of 3 s.

much difference observed for the stress–strain curve for the melt temperatures of 230 and 240°C for both the experiment and simulation results. However, there was a 50% increase in strain in plastic deformation with the 250°C melt temperature. The same observations recorded for the sample with a 5-second holding time are shown in Fig. 15.

Flax fiber-reinforced PP copolymer

Figs. 16 and 17 show the simulated and experimental stress–strain curves for the flax fiber-reinforced PP copolymer with melt temperatures of 230, 240, and 250°C and holding times of 3 and 5 s. The strain increment was more than 100% for plastic deformation with melt temperatures of 240 and 250°C. With the 5-second holding time, as the melt temperature increased, the strain percentage for plastic deformation increased (Fig. 17). This indicates that the higher the melt temperature, the greater the strain.

Fig. 15 Simulated and experimental stress–strain curves. Rice husk fiber-reinforced polypropylene (PP) copolymer. Melt temperatures of 230, 240, and 250°C. Holding time of 5 s.

Fig. 16 Simulated and experimental stress–strain curves. Flax fiber-reinforced polypropylene (PP) copolymer. Melt temperatures of 230, 240, and 250°C. Holding time of 3 s.

Fig. 17 Simulated and experimental stress–strain curves. Flax fiber-reinforced polypropylene (PP) copolymer. Melt temperatures of 230, 240, and 250°C. Holding time of 5 s.

Fig. 18 Simulated and experimental stress–strain curves. Coconut shell fiber-reinforced polypropylene (PP) copolymer. Melt temperatures of 230, 240, and 250°C. Holding time of 3 s.

Coconut shell fiber-reinforced PP copolymer

The simulated and experimental stress–strain curves for the coconut shell fiber-reinforced PP copolymer at melt temperatures of 230, 240, and 250°C with 3 s of holding time are shown in Fig. 18. As the melt temperature increased, the stress decreased drastically to more than 70%, indicating that the coconut shell fiber-reinforced PP copolymer had decreased strength due to the increased processing temperature. Therefore, it is better to mold parts made from coconut shell fiber at lower melt processing temperatures to maintain their strength.

Based on Figs. 14–18, the experimental and simulated FEA results displayed identical trends for the three natural fiber-reinforced PP copolymers with different combinations of processing parameters. The curves obtained from both results were in similar trend. All simulated models provided good agreement with the experimentally tested method. Hence, the simulated models used for ABAQUS simulation can be used to simulate the tensile test with other conditions, such as different testing speeds. In other words, it was proven that the results obtained using ABAQUS were theoretically accurate.

Conclusions

Tensile testing for three types of natural fiber-reinforced PP copolymers was conducted experimentally and also simulated by using FEA software (ABAQUS). The mechanical properties for these three types of natural fiber-reinforced PP copolymers were also investigated. The results of this study provide the following conclusions:

1. The flax fiber-reinforced PP copolymer possesses better stiffness and can withstand more stress while being stretched or pulled than the other two natural fiber-reinforced PP copolymers.
2. Processing parameters affect the mechanical properties of the microtensile specimen. In this study, the effect of melt temperature on the tensile strength of the microtensile specimen was significant for flax fiber-reinforced and rice husk fiber-reinforced PP copolymers.
3. The simulated results of tensile testing were compatible with the experimental results. The results of both produced similar curve trends. Therefore, for the same material, the simulated model can be used to simulate tensile testing with different conditions.

Introduction

Today, there is an expanding demand worldwide for the advanced materials with a specific end goal to get the coveted properties. This is because that a solitary material by and large can't meet the necessities of cruel engineering conditions. That is the reason the requirement for metal matrix composites (MMC's) with extraordinary properties (high strength, high stiffness and low weight) compared to monolithic material is developing every day (Kok, 2005). MMC's are made from two or more diverse metals, inter-metallic compounds (reinforcement) in which scattered stages are implanted inside the metallic matrix. The ceramic reinforced MMC's exhibit better tribological properties due to the shielding of matrix (soft metal) with reinforcement (hard ceramic) particles (Suresha and Sridhara, 2010). The insoluble reinforcement size, kind, their relative amount controls the properties of the composites.

Among all MMC's, Aluminium metal matrix composites (Al-MMC's) have found wide applications in today's fast growing automobile and aviation industry (Singh *et al.*, 2015b). There are a few preferences in utilizing particles reinforced Al-MMC's materials than un-reinforced/monolithic materials (cast iron, steel) such as- more prominent strength (tensile strength) with less weight, progressed stiffness, low thermal extension coefficient, high thermal conductivity, increased wear resistance, improved mechanical properties (hardness) and made strides damping capabilities (Surappa, 2003). Al-MMC's are very promising materials for foresaid industry not only due to their excellent combination of properties, but also can be processed by conventional manufacturing processes such as forging, rolling, extrusion and subsequent machining (Iqbal and Nuruzzaman, 2016). Al-MMC's based components are mostly used in tribological system which needs excellent wear performance. It has been observed that the hard non-metallic and ceramic particles like SiC, Al₂O₃, B₄C, Gr etc. have been successfully used as reinforcements in Al-MMCs to impart excellent mechanical and tribological properties (Sahin, 2003; Kok and Ozdin, 2007; Das *et al.*, 2007; Yigezu *et al.*, 2013). The lower weight of Al-MMC's material based engine components reduces the fuel consumption in automobile and aircraft which further reduces the air pollution (Surappa, 2003). In 1992, UK Advisory Council on Science & Technology expressed that the Al-MMC's could be able to swap for existing materials with superior properties (Surappa, 2003).

The new generation hybrid Al-MMC's development with the incorporation of more than one type, shape and size of reinforcement into a single matrix (Al) are gaining more importance (Matsunaga *et al.*, 1996). Hybrid Al-MMC's have the potential to fulfil industry requirement due to their superior properties (tribological and mechanical) as compared to single reinforced composites (Ahlatci *et al.*, 2006), since it is troublesome to consolidate a wide range of properties within the composite materials with single reinforcement. Bindumadhavan *et al.* (2001) reported that the dual particle size (DPS) reinforced A356/SiC composite exhibit better wear resistance as compared to the single particle size (SPS) reinforced composite due to shielding of smaller SiC particles by larger one in DPS. Whereas, Maleque and Karim (2008) had observed that the triple particle size (TPS) Al/20% SiC exhibited better wear resistance properties compared to DPS reinforcement. The effect of multiple particle size (80 µm, 40 µm and 15 µm) of SiC reinforced Al-MMC on the wear characteristics was also investigated and observed that coarse particle has significantly influence the wear resistance as compared to the intermediate and fine particle sizes (Abdulmumin *et al.*, 2015).

The hybrid material gives more freedom to design a material for any specific application with less cost. Hybrid Al-MMC's have better wear resistance and high specific strength with less weight due to which it is widely used in automotive engineering applications such as: piston rods, piston pins, pistons, brake discs and pads, shaft, etc. (Uvaraja and Natarajan, 2012). The improved tribological properties of hybrid composites have made it more suitable choice for structural application in the aerospace industry.

The fabrication process and the reinforcement (type, shape, size & quantity) governed the properties of the composites (Hashim *et al.*, 1999; Surappa, 2003). The target properties can be successfully achieved by getting requisite wetting, bonding and stability among the matrix and reinforcement (Hashim *et al.*, 1999) with a homogeneous distribution of the reinforcement in the matrix. The diverse processing route has been adopted to fabricate Al-MMC's such as:

- (1) Solid state processing route (Powder metallurgy, Diffusion bonding and Physical vapour deposition),
- (2) Liquid state processing route (Stir casting, Infiltration process and Spray deposition).

The stir casting (SC) is one of the most preferred economical liquid state processing route among the all processing routes due to its simplicity, flexibility and suitability for large scale production (Surappa, 1997). In SC, the reinforcement particles are uniformly mixed in a molten metal (matrix) with a mechanical stirrer (see Fig. 1), then further the molten mix (matrix and reinforcement) is poured into die in the case of die casting or mould in case of sand casting. The cost of production associated with

Fig. 1 Metal Matrix Composites through SC.

SC is one third as compared to other process (Surappa, 1997; Shankar *et al.*, 2013) and make this is the first choice for large scale production.

The cast component needs an additional machining process to get the exact size and shape which may become difficult due to the presence of abrasive reinforcement in the Al-MMC's casting. It has been found that the subsequent high cost and time is required for the development and modification of the pattern in sand casting. So, to overcome the limitations of conventionally used fabrication process the synergistic combination of rapid prototyping processes with the modern casting technique V-process which can greatly contribute towards decreasing the lead time while maintaining the quality standards is introduced in this study.

Rapid Manufacturing of Patterns

It is well established that large range of metal parts are manufactured with sand casting for many years. The pattern is the key element of the casting process used to create the cavity with desired feature. A lot of conventional manufacturing processes (turning, milling, drilling etc.) are involved to develop the pattern. During prototyping which involved development of the product and its performance testing, excessive time is involved in the manufacturing of product pattern. Whereas in case of customized based product manufacturing in which the required quantity is very limited excessive lead time is consumed in the development process. Along with excessive development time high level skill is also required for the development of pattern with conventional process. The major concern for today's industry is to remain competitive in the market and which is not possible without reducing the product development cycle time. Hence, there is strong motivation to incorporate rapid prototyping (RP) technology for the development/manufacturing of pattern. However the major limitations related to RP for this purpose are size of component and the high cost of infrastructure. The use of RP introduced few decades ago gives new look to this sector and emerged as rapid tooling for the manufacturing of application oriented product in less time. RP is entirely CAD and modeling software based process to develop a 3D model of the product. With the application of computer the CAD based data are split into slice/layer which further develops the object layer wise. RP process is effectively able to reduce the product development cycle with efficiently controlling the development time and human interaction in comfortable work conditions. Due to these excellent features RP is not limited to manufacturing industry now it becomes a prominent field of research. The practice of RP technique to develop rapid tooling provides a platform for the development of functional based product particularly for medical research.

RP can be able to manufacture multiple and complex geometry part in single build without changing tool and with a minimum skill requirement. Among all the RP techniques, Fused Deposition Modeling (FDM) developed by Stratasys Inc. is widely accepted for rapid manufacturing of the pattern, wherein a plastic filament of Acrylonitrile-Butadiene-Styrene (ABS) material is used. It is also reported that the FDM has significantly reduced the product development time and cost and become the first choice of the researchers (Bakar *et al.*, 2010; Chohan *et al.*, 2017).

FDM is a rapid prototyping technology suited for producing parts with complex geometries. The FDM machine is basically a computer numerically controlled gantry machine, carrying two miniature extruder head nozzles, one for the modeling material and the other for the support material (Sun and Rizvi, 2008). In the FDM process, parts are fabricated by extruding a molten filament through a heated nozzle in a prescribed pattern onto a platform (Fig. 2). As the material is deposited, it cools, solidifies and bonds with the adjoining material. When one whole layer is deposited, the base plate moves down by an increment equal to the height of the filament and the next layer is deposited. FDM prototypes can be viewed as composites structures composed of partially bonded filaments. A key feature of the FDM process is its potential to fabricate parts with locally controlled properties such as porosity, density and mechanical properties (Li *et al.*, 2002). FDM requires minimal manpower and is increasingly used to fabricate customized products for engineering as well as medical applications (Singh *et al.*, 2018a). The several applications of FDM generated parts are illustrated in Fig. 3.

Singh *et al.* (2017b) established that the manufacturing of customized biomedical implant (hip joint) is feasible through the combined route of FDM (to develop pattern), chemical vapour smoothing (to improve surface finish), vacuum casting and

Fig. 2 Schematic of FDM setup.

Fig. 3 Application of FDM parts. Reproduced from Singh, J., Singh, R., Singh, H., 2017a. Dimensional accuracy and surface finish of biomedical implant fabricated as rapid investment casting for small to medium quantity production. *Journal of Manufacturing Processes* 25, 201–211.

investment casting. The combined processing route was successfully delivered adequate dimensional accuracy and surface finish to the implant. Further, the tolerance grade of the selected dimension of the casting (implant) was found in accordance with ISO standard UNI EN 20286-1 (1995).

V-process/Vacuum Moulding (VM)

The quality of the product and its control is the prime requirement of the manufacturing industry. The metal casting industry is also growing continuously with the aim of consistent quality production to survive in this fast developing competitive industry. To overcome the limitation of the conventional moulding process such as heavy machinery, casting defects (blow hole, poor surface finish) and pollution, V-process/vacuum moulding (VM) has emerged as one of the modern technique to deliver adequate quality with minimal defects (Kumar *et al.*, 1999).

The vacuum sealed moulding/V-process was invented and patented by the Japanese in 1971 and introduced to the foundry men in 1972 (Bishop and Bose, 1983; Clegg, 1985). First V-process plant was successfully commissioned for commercial production under the able leadership of Dr. R. Kono at Toyokawa works of Sinto (Japan) in 1972 (Clegg, 1985). VM has received significant importance due to its potential to create dimensionally precise, smooth casting and high return rate of sand at 95% (Kumar *et al.*, 1999). The fundamental distinction among VM and conventional sand moulding processes is the manner wherein sand is bounded to form the mould cavity. VM entails the formation of mould cavity via thermal and vacuum forming of plastic film over the pattern, backed by dry un-bonded sand compacted by mean of vibration and further gets encapsulated between plastic films under the influence of imposed vacuum (250–450 mm Hg) (Clegg, 1985). On pouring, the molten metal fills the cavity under vacuum, precisely duplicating all of the features. The vacuum was maintained until the metal solidifies and the sand was dropped away very easy to leave the casting with the

fine surface finish. The casting produced by this green process is free from draft allowance with a high degree of dimensional accuracy which further helps to reduce the machining time and cost (Regnet, 2000). VM has also retrenched the high investment on the dies and equipment as compared to the die casting process. In VM, cracking defect encountered in die casting is also eliminated due to the good withdrawal ability of the unbounded sand. VM is emerging as environment friendly process as compared to conventional sand casting due to the absence of pollution caused by the burning of the binder and reuse of moulding sand without further treatment (Jain and Gaindhara, 1986; Barua *et al.*, 1996; Grefhorst and Muller, 2000; Singh *et al.*, 2017c). The lower solidification rate of metal in a vacuum mould also promotes the development of fine grain microstructure and further causes improvement in the mechanical properties of the cast components (Kubo *et al.*, 1973; Kumar and Gaindhara, 1997). Singh and Singh (2015) prepared Al-MMC's consisting of Al-6063(matrix) reinforced with SiC (SPS-100 μm ; DPS-100 and 120 μm ; TPS-100, 120 and 150 μm) in the proportion of 5 wt%, 7.5 wt% and 10 wt% through FDM based pattern and vacuum assisted SC. The tribological performance of the developed Al-MMC's was examined on the basis of dry sliding wear test by using a pin-on-disc (ϕ 8 mm $\times$ 25 mm) at sliding speed of 239 rpm, sliding diameter of 80 mm and a load of 19.61N for 10 min. The effect of V-process assisted SC parameters (particle size of SiC, the proportion of SiC, vacuum pressure and sand grain size) on wear performance of Al-MMC's were also studied. The study highlighted the percentage contribution of sand grain size, vacuum pressure, particle size of SiC and composition for wear are 5%, 10.14%, 10.71% and 73.2%, respectively. Singh *et al.* (2015a) have examined the effect of particle size of hybrid reinforcement (fixed proportion, 10% by weight.) Al_2O_3 and SiC on wear performance of Al-MMC prepared by SC and VM. The result shows that the particle size of hybrid reinforcements have greatly influenced (70%) the wear performance of casted composites and the single particle size (SPS) hybrid reinforced composite exhibits better wear resistance. Singh and Singh (2017) have successfully developed Al- Al_2O_3 based biomedical implant (dynamic condylar screw) by using the combined process comprising of FDM, VM and stir casting. The contribution and optimum level of various process parameters (percentage composition of Al and Al_2O_3 , vacuum pressure and grain size of silica) towards micro hardness of the implant was investigated. The study highlighted the moulding sand (74%) is most contributing factor followed by vacuum pressure(14.73%) and Al_2O_3 composition(6.2%) and prosed the best parametric setting (Al_2O_3 5%, AFS no. 60 and vacuum pressure 300 mm of Hg) for maximum micro hardness.

Singh *et al.* (2018b) developed Al-MMC's with hybrid reinforcement (5%, 7.5% and 10% by weight) of double particle size (DPS) and triple particle size (TPS) Al_2O_3 and SiC, by using VM (V-process) assisted SC process and examined the process capability of the hybrid process in term of dimensional accuracy. The study highlights the percentage contribution of significant process parameters (particle size 9.19%, type of reinforcement 12.99%, vacuum pressure 35.18% and moulding sand grit size 28.10%) on the dimensional accuracy of hybrid Al-MMC. Finally the calculated value of process capability indices (Cpk) more than 1.3 highlighted that the developed hybrid process is statistically controlled for batch and mass production.

Considering the novel features of FDM and V-process/VM (VM) a synergistic combination of FDM and VM can be explored as new route for the development of hybrid Al-MMC's. The resulting green process will lead to rapid casting solutions for metal matrix composites (MMC's). It is quite evident in the literature that the Al-MMC's are widely used in the tribological application. So, in the present study attempt has been made to examine the process capability of this novel route in term of the performance characteristics such as wear, micro hardness and dimensional accuracy of the hybrid Al-MMC's.

Procedure to Develop Hybrid Al-MMC's

The brief description about the procedure to develop hybrid Al-MMC's with the novel fabrication route including FDM, VM and SC process is as mentioned below:

Development of pattern with FDM: After selecting the component/benchmark, the CAD file of the selected component was exported into STL (Standard Triangulation Language) format and sliced down on Catalyst-EX[®] FDM system inbuilt software. The perforated ABS pattern of the selected component was printed on FDM machine with tiny holes (ϕ 1 mm) to induce vacuum suction for the proper sticking of plastic film during the V-process.

Mould formation with VM: FDM based pattern is used to create mould with V-process/VM, the schematic view of VM setup is shown in Fig. 4.

For the mould formation, the perforated pattern (of selected component) is placed at the centre of the base plate and a preheated thin plastic sheet was drawn onto the pattern contour by imposing vacuum (300–400 mm of Hg), as shown in Fig. 5(a). Then a mould box (drag) was placed on the base plate and the formed plastic sheet was fixed with the mould box (Fig. 5(b)). The dry un-bonded silica sand (AFS No. 50–70) fills in the mould box and gets compacted by vibration (3–5 s), as shown in Fig. 5(c). The other open side of the mould box was sealed with second plastic sheet and then further vacuum was applied to compact the sand (Fig. 5(d)). The vacuum of the base plate was released and the mould box flipped off. The pattern easily slipped out and the required cavity/mould was formed (Fig. 5(e)). After developing mould/cavity, place second mould box (cope) on the first mould box (Fig. 5(f)). Fig. 5(g) shows, the proper gating arrangement given to the formed cavity. The mould box (cope) was filled with dry unbounded sand and sealed with a plastic sheet (Fig. 5(h)). The sand gets compacted with the application of vibration and vacuum. The two halves were properly sealed and the mould cavity under vacuum was ready for metal pouring.

Fig. 4 Schematic of VM setup. Reproduced from Singh, R., Singh, S., Hashmi, M.S.J., 2017c. Vacuum molding. In: Hashmi, S., (Ed.), Reference Module in Materials Science and Materials Engineering. vol. 13. Oxford: Elsevier, pp. 1–18.

Preparation for hybrid Al-MMC's with SC: For the development of Al-MMC, the required quantity of aluminium alloy was melted in a graphite crucible at 800°C and the reinforcement particles (SiC and Al₂O₃) were preheated at 450°C to drive off the moisture before charging. A mild steel stirrer is immersed up to two thirds depth of the molten metal and stirred at the speed of 450 RPM (Fig. 6(a)). Finally, the molten Al-MMC was poured into the mould under negative pressure and get solidify (Fig. 6(b) and (c)). Fig. 6(d) shows, after cooling the vacuum is released and free-flowing sand drop away, leaving a clean required casting without sand lumps.

Case Study

In order to develop hybrid Al-MMC's through synergistic combination of FDM, VM and SC investigate and validity of this novel route has been established by examine the process capability in term of the performance characteristics such as wear, micro hardness and dimensional accuracy of casting, a case study has been discussed.

In the present case study, a disc of 50 mm diameter and 10 mm thickness was selected as a component/benchmark (see Fig. 7) and the perforated ABS pattern of the selected component was printed on FDM machine. The FDM based pattern was used to create mould with VM, the performance characteristics of the casting obtained through VM are governed by the various input control factors of the process such as vacuum pressure (mm of Hg); moulding sand grit size (AFS No.); and vibration time (s). Based upon the various trails the best parametric setting of VM considered for this study is given in the Table 1.

For the development of Al-MMC, aluminium alloy Al-6063 alloy (≥ 99.6 wt% Al) was used as a matrix material and Al₂O₃ and SiC of particle size 122 μ m and 102 μ m are used as reinforcement. The detailed chemical composition of matrix (Al-6063) and the properties of reinforcement (Al₂O₃ and SiC) are given in Tables 2 and 3, respectively. The particle size and composition of reinforcement strongly affect the tribological performance (wear) and mechanical properties (micro hardness) of the Al-MMC's. In the present study, reinforcement composition of 10 wt% with double particle size (DPS) was used, the DPS reinforcement was obtained by mixing of 122 μ m and 102 μ m particle size in equal proportion by weight. The parametric setting of stir casting employed for the present case study is given in Table 4.

Six repetitive trials were conducted at the selected parametric setting of VM (Table 1) and SC (Table 4) by following the procedure explained in Section "Procedure to Develop Hybrid Al-MMC's". The performance characteristics (wear, micro hardness and dimensional accuracy) of the casted discs were examined.

Wear Test: As per ASTM G 99 standard, testing pin of size $\phi 8$ mm $\times$ 25 mm was prepared from all the casting. The contact surface of the pins was polished on 800 grit emery paper. Wear test pins were slides against EN-31 steel disc hardened to 60 HRC and ground to 1.6 Ra. Tests were conducted at constant conditions of normal load, sliding track diameter and sliding speed of 30 N, 100 mm and 1 m/s, respectively, for 10 min. Three repetitions of experiments were conducted to minimize the error and the corresponding results of tests for wear (μ m) were obtained, as given in Table 5.

3	70.9	41.1	0.75
4	70.2	40.6	0.73
5	70.7	41	0.71
6	70.4	40.8	0.71

Fig. 6 Preparation for hybrid Al-MMC using SC.

Hardness Test: Micro hardness of the Al-MMC's based castings was examined by using computerized Vickers hardness tester as per ASTM E384.A load of 0.1 N was applied for 10 seconds on polished specimens of composites developed under ambient laboratory conditions. Each hardness value reported is an average of three readings, as given in [Table 5](#).

Dimensional Accuracy: Dimensional accuracy in term of dimensional deviation examined the capability of the process to regenerate the dimensions/features as per design. Thickness of the disc was selected for this study and dimensional

Fig. 7 Dimensions of benchmark disc.

Fig. 8 Process capability histogram for wear.

deviation (Δt) of each casted Al-MMC's disc of designed dimension ($t=10$) was calculated. Thickness of the disc was measured from different points and an average value of dimensional deviation (Δt) of each casting is presented in Table 5.

Process Capability: After the satisfactory results, the development process of hybrid Al-MMC's and its performance characteristics (wear, micro hardness and dimensional deviation) were further examined to understand whether the developed process is statistically controlled or not? The process capability analysis of the process under study has been visualized through the process capability indices (C_p and C_{pk}). Minitab-17 software was used to plot process capability histograms and to determine process capability indices.

The histogram plot illustrating process capability indices for wear, micro hardness and dimensional deviation are shown in Figs. 8–10, respectively. The calculated value of process capability indices for each performance characteristics are tabulated in Table 6 and found the value of each process capability indices is greater than 1. The process with C_p and C_{pk} values of 1 or greater 3 indicated that the proposed process is statistically controlled and generally recommended for industry benchmarks which can be further improved under closed monitoring.

Thus, the process capability study based upon process capability indices deduced that the synergistic combination of FDM, VM and SC is quite capable in producing dimensionally accurate castings of hybrid Al-MMC's with adequate wear resistance and micro hardness. There is high probability for this process to be statistically stable and controlled for batch and medium production.

Table 6 Process capability indices for wear, micro hardness and dimensional deviation

Process capability indices	Performance characteristics		
	Wear	Micro hardness	Dimensional deviation
C_p	1.10	1.16	1.17
C_{pl}	1.10	1.16	1.22
C_{pu}	1.10	1.16	1.11
C_{pk}	1.10	1.16	1.11

Conclusions

The significance of the present study is to explore the feasibilities of the development of Al-MMC's with hybrid reinforcement by using the synergistic combination of FDM, VM and SC. The results of the study also established the competences of the new processing route for developing Al-MMC's with hybrid reinforcement (10 wt%) of DPS Al_2O_3 and SiC. The process capability histogram plot for wear, micro hardness and dimensional deviation illustrating that the process capability indices (C_p and C_{pk}) of each performance characteristic is greater than 1 confirmed that the process under study is statistically controlled. Thus, the proposed process is recommendable for industry benchmarks.

Introduction

Ceramics are the first man made materials (Bhargava, 2011) having excellent mechanical, chemical, thermal and structural properties (Bhosale *et al.*, 2014). However, owing to its brittleness and bad electrical properties it is not possible to use ceramics in their natural form for various engineering applications. Therefore, the primary objective to make ceramic matrix composites is to overcome those deficiencies which can be a barrier in its applicability to different applications. Composite is basically a compound which contains a matrix phase and reinforcement phase (Vasiliev and Morozov, 2001).

CMCs obtained by different processing methods are generally having better wear properties, excellent creep behavior, fracture toughness and more resistant to thermal shocks. The basic purpose of reinforcement is to distribute stresses to nearby areas of crack tip which helps to alleviate the intensity of crack propagation (Callister, 2001). Due to this, CMCs are mostly preferred to use in the severe and hard environmental conditions where high thermal shocks and temperature is involved. The use of CMCs are generally in the field of aerospace, cutting tools, brakes, heat exchangers, gas turbines and many more. (Kaya, 1999; Chawla, 1995). The commonly used reinforcements for the CMC's are boron nitride (BN), titanium nitride (TiN), titanium carbide (TiC), carbon nanofibres (CNF), carbon nanotubes (CNT's), graphene and carbon black. Fabrication of ceramic composites can be done in different ways (see Fig. 1).

Fabrication by Using Gas Phase Processes

This process involves the controlled chemical reaction between the matrix and reinforcement material to form a composite. Few examples of gas phase reaction processes are chemical vapor deposition (CVD), reaction bonding and chemical vapor Infiltration (CVI) processes. This process has certain benefits over the other processes such as less processing time, temperature as well as lower energy requirement for nucleation and growth, and increased densification rate and capability to produce near net shape (Chiang *et al.*, 1991; Rahaman, 2003; Weimer *et al.*, 1997; Maitra, 2014). But, the major problem that arises during the formation of composite using gas phase processes is the increased porosity which deteriorates the mechanical properties of composites (Chiang *et al.*, 1991; Rahaman, 2003; Weimer *et al.*, 1997; Maitra, 2014; Yarbrough and Messier, 1990; Han *et al.*, 2014). Fig. 2 shows the set-up of commercial CVD system.

Fabrication by Using Liquid Phase Processes

Liquid phase processes primary include Sol-gel (see Fig. 3) and Polymer infiltration pyrolysis method. In this method, first step is to infiltrate the required polymer with the fiber reform in order to manufacture CMC's. Second step is the consecutive curing and pyrolysis to form a highly porous matrix, which is undesirable for most applications. Third stage involved polymer infiltration and pyrolysis up to number of cycles until the final product with better quality is achieved. It usually takes five to eight cycles to achieve best results (Ziegler *et al.*, 1999; Kotani *et al.*, 2003; Rocha *et al.*, 2006). Low yield and increased shrinkage volume and time to form a highly dense composite are the major drawbacks of this process (Rosso, 2006). In addition to this, crack formation during drying process in the matrix is another demerit of this process (Zou *et al.*, 2012; Almeida *et al.*, 2015).

Fabrication by Using Solid Phase Processes

Powder metallurgy is one of the solid processing methods which include the mixing and blending of different powders with required binders and lubricants, followed by the compaction of mixed powder and in the last sintering of the compact under controlled condition (Angelo and Subramanian, 2012). Powder metallurgy is used for the production of different parts from ferrous and non ferrous materials. This method is best suitable for the materials having low ductility and high melting point and for the materials which otherwise are not suitable for casting processes (Callister, 2001). Whereas in slip casting method, reinforcement is put into the matrix melt and time is allowed to solidify. The materials having different specific gravities can be easily mixed together by using slip casting process (Shiono and Noda, 1997).

Limitation to form simple shapes with specific dimensions, poor grain growth and mechanical properties are some of the disadvantages of the solid processing methods (Wang *et al.*, 2006; Zhang *et al.*, 2010). Table 1 shows the detailed comparison of different fabrication processes.

Fig. 1 Methods employed for fabrication of ceramic composites. Reproduced from Rayat, M.S., Gill, S.S., Singh, R., Sharma, L., 2017. Fabrication and machining of ceramic composites – A review on current scenario. *Materials and Manufacturing Processes* 32(13), 1451–1474.

Fig. 2 Commercial CVD system. Reproduced from Weimer, A., Besmann, T., Stinton, D., Lowden, R., Lee, W., 1996. Chemical vapor deposition (CVD) and infiltration (CVI). *Carbide, Nitride Boride Material Synthesis Process*, 547–577.

Machining of Ceramic Matrix Composites

The primary disadvantage of the different fabrication methods is that they are not able to produce accurate geometrical shapes due to shrinkage and other fabrication limitation (Jianxin and Taichiu, 2000; Li *et al.*, 2005). So, further need for machining is required either by traditional or by modern machining methods. Drilling and grinding are the most commonly used traditional methods for the machining of ceramic and its composites (Rayat *et al.*, 2017). But there are number of different non traditional machining processes which are used for machining (Pawar *et al.*, 2015) and listed below.

- (1) Ultrasonic machining: This machining process is based on the ultrasonic frequency and the material removal takes place with the help of mechanical abrasion.
- (2) Laser beam machining: This process uses thermal energy for the removal of material and suitable for both conductive and non-conductive materials.
- (3) Abrasive jet and abrasive water jet machining: In this process abrasive particles with the help of carrier medium either water or gas are made to strike on to the workpiece to remove material.
- (4) Electrochemical discharge machining: In this machining process instead of dielectric, electrolyte is used to machine the non conducting materials.
- (5) Electron discharge machining: This machining process involves the machining of material in the presence of dielectric and only suitable for electrical conductive materials.

Literature Review

Zhu *et al.* (2008) fabricated a $\text{ZrB}_2\text{-B}_4\text{C}$ particulate ceramic composite by using microwave sintering technique and found that as the temperature of sintering increased from 1630°C to 1720°C there was a rise in the relative density. Above temperature 1700°C

Fig. 3 Schematic of sol- infiltration set-up. Reproduced from Naskar M.K., Basu, K., Chatterjee, M., 2009. Sol-gel approach to near-net-shape oxide-oxide composites reinforced with short alumina fibres – The effect of crystallization. *Ceramic International* 35(8), 3073–3079.

Table 1 Comparison of different fabrication methods

S.No.	Route	Advantages	Disadvantages	Cost	Temperature
1	Reaction bonding	● Near net shape ● Low processing time ● High densification properties	● Limited to simple shapes ● High porosity	High	Up to 1700°C
2	Chemical vapor deposition	● Enhanced mechanical properties ● High deposition rate ● Applicability to number of materials	● Hazardous by- product produced during chemical reaction ● Leads to stresses in films due to difference in thermal expansion co-efficient	High	Up to 1600°C
3	Chemical vapor infiltration	● Flexibility in selecting fibers and matrices ● Complex shapes can be produced ● Uniformity and purity of matrix	● Low processing time ● High residual porosity ● Low production rate	High	Up to 1800°C
4	Sol-gel and polymer Infiltration pyrolysis	● Better control over matrix composition ● Densification temperature is less	● Long processing time ● Multiple iterative processes to obtain dense structure ● Low production rate ● Crack formation in matrix during cooling phase	Low	Up to 1400°C
5	Powder processing	● Simple and complex shapes can be formed depending upon the sintering process ● High densification properties ● Good mechanical properties ● Rapid process	● Uniform distribution of reinforcement into matrix phase is difficult task ● High processing temperature ● Chances of damage to reinforcement during compaction process	Medium	Up to 1800°C

Note: Rayat, M.S., Gill, S.S., Singh, R., Sharma, L., 2017. Fabrication and machining of ceramic composites – A review on current scenario. *Materials and Manufacturing Processes* 32(13), 1451–1474.

for conventional and microwave sintering nearly fully dense composite was formed. Minimum grain growth was observed in case of microwave sintering.

Wang *et al.* (2010) prepared and characterised a ceramic composite at ultra high temperature by microwave sintering. During his experimentation he found that when the percentage of SiC (whiskers and nano particle) reached at 30% the relative density

almost reached at 100% and the addition of SiC improved the densification. From microstructure it was revealed that the increasing volume fraction of SiC inhibited the grain growth of ZrB_2 and it also affects the fracture surfaces. The mechanical properties such as flexural strength and fracture toughness increased up to a percentage of 30% of SiC but after that decreases due to the formation of agglomeration.

Cheng *et al.* (2014) studied the feasibility of producing alumina and titanium carbide micro composite having better micro structural and mechanical properties by using microwave sintering at different operating temperature. The relative density of the composite increase with respect to the increase in sintering temperature and it reaches to maximum of 99% at temperature of 1600°C due to the presence of liquid phase produced by MgO and microwave electromagnetic energy. XRD confirms that there is no chemical reaction take place between alumina and titanium carbide which leads to formation of pores and ultimately affects the mechanical properties. Improvement in fracture toughness and Vickers hardness number were also reported.

Cha *et al.* (2005) studied the fabrication of Alumina and CNT nanocomposites through molecular level mixing in conjunction with spark plasma sintering (SPS) and found that the strength and fracture toughness enhanced due to bridging effect. Strength of nanocomposites increased up to 1% of CNT but start decreasing as the percentage increased more above 2% due to agglomeration.

Inam *et al.* (2010) has done the characterization of electrically conductive alumina-carbon nanocomposites prepared by spark plasma sintering. The electrical conductivity of Alumina- CNT (2 wt%) is more as compare to alumina- Carbon black nanocomposites of same wt% due to the large aspect ratio of CNT and also due to undamaged CNT during SPS method. Electrical conductivity also depends upon grain size as the grain size increases grain boundary area decreases. Some agglomeration was observed in alumina- carbon black nanocomposites material which was the reason for isolation of carbon black nanocomposites particulate. Good dispersion was found in case of CNT – Alumina material due to its fibrous nature which also effect electrical conductivity.

Hvizdos *et al.* (2012) had studied the tribological and electrical properties of ceramic matrix composite doped with CNT and carbon nanofibres. The relative density was more effective when the ceramic matrix composite fabricated through spark plasma sintering as compared to hot pressing. As compared to CNT coefficient of friction was effectively decreased with the addition of carbon nanofibres which act as a solid lubricant. Electrical conductivity also proved to be increased effectively with the addition of small amount of CNF as compared to CNT.

Hirota *et al.* (2007) fabricated carbon nanofibre (CNF) and alumina by using pulsed electric current pressure sintering (PECPS) and investigated mechanical properties and electrical properties. At 5.95% vol of CNF there was a consistent increase in bending strength and fracture toughness but decrease in hardness value due to weak cohesion bonding forces between CNF and Alumina. Agglomeration and dispersion was observed as a factor of particle size and zeta potential and concluded that good dispersion could be achieved by using small particle size. Bulk density and relative density decreased as the percentage of CNF in Alumina increased.

Zhang *et al.* (2010) fabricated alumina and carbon nanotube by pressure less sintering and found that the highest relative density was achieved at a temperature of 1500°C for time duration of 2 h. Flexure strength was increased which results due to pinning affect of CNT which inhibits the grain growth in the alumina composite. Fracture toughness was also increased due to CNT pullout phenomenon.

Shi *et al.* (2011) investigated the effect of CNF reinforced aluminium nitride composites prepared by plasma activated sintering on the mechanical and electrical properties and found that with higher percentage of CNF the relative density of the composite decreased due to restriction on the rearrangement of AlN particles. Similarly high percentage of CNF leads to decrease in the mechanical properties such as fracture toughness, hardness, flexure strength etc. which may be due to weak interfacial bonding between CNF and AlN that weakened the crack bridging effect. DC conductivity of the specimen considerably increased for small percentage of CNF.

Hanzel *et al.* (2014) studied the new approach for the distribution of carbon nanotubes in Al_2O_3 . During his experimentation he found that granulated homogenous mixture was formed which was necessary for the improvement in electrical conductivity and other mechanical properties. The highest electrical conductivity was achieved when 10 vol% MWCT added. Fracture toughness increased as the percentage of CNT content increased due to bridging of cracks and pull out mechanism. Vickers hardness value decreased due to the lower hardness value for carbon nanotubes.

Michalek *et al.* (2014) fabricated and characterised the alumina/MWCNT and alumina/zirconia/MWCNT composites. The relative density was slightly more in case of alumina/zirconia/MWCNT as compared to alumina/ MWCNT composite due to the refined microstructure and pinning effect. The hardness value decreased due to formation of agglomerates, coarse grained microstructure and weak interfacial bonding. The fracture toughness increased in both composites. The electrical conductivity was achieved where high percentage of MWCNT was added.

Jianxin and Taichiu (2000) compared the surface integrity obtained in electro- discharge machining, ultrasonic machining and diamond saw cutting of ceramic composites. Ceramic composites surface indicates that the thermal spalling, brittle fracture and brittle fracture during chipping occurred in case of EDM, Ultrasonic machining and diamond saw cutting machine respectively. Surface roughness value was high in case of EDM due to surface cracks, craters and droplets. Better quality surface was obtained in USM and diamond saw cutting.

Muttamara *et al.* (2003) has performed experiment to find out the probability of precision micromachining of insulating Si_3N_4 ceramics by electric discharge machining. Two different layers have been used as assisting electrode out of these carbon baked layer was most effective. Material removal rate was greatly affected by the tool diameter. Machining properties depends on the area effects of tool electrode size and generation of concentration discharge waveform.

Lauwers *et al.* (2004) investigated the material removal mechanism in EDM of composite ceramic materials. Three different material removal mechanisms were identified such as melting, spalling and oxidation which were confirmed through the analysis of debris and surface quality. Cracks were generally formed by spalling and also it depends on the material properties such as thermal conductivity, fracture toughness, melting point and strength. Spalling effect was not in case of ZrO_2 – TiN specimen having high fracture toughness.

Zhang (2004) studied the effect of wire electric discharge machining parameters on the surface integrity of the nanocomposites ceramic. Material removal rate was evaluated as a function of power transistor number as the power transistors increases the MRR was also increased. MRR decreases as the pulse off time value increases. From the surface analysis it was found that surface roughness also depends upon power transistor number, large craters were formed when using more number of power transistors. From EDS spectrum analysis and XRD analysis it was found that some amount of tool material was transferred to the machined surface due to melting and solidification during spark formation.

Fukuzawa *et al.* (2009) performed the three dimensional machining of insulating ceramics material with electrical discharge machining and found that as the open circuit voltage increased the material removal rate also increased but the bending strength of material decreased. The thickness of the conductive layer also increased while increasing open circuit voltage and the layer consists of wire tool electrode and workpiece material.

Tak *et al.* (2011) has done the characteristics evaluation of alumina and carbon nanotube (CNT) for micro electric discharge machining and found that electric conductivity of material depends upon the percentage of CNT, as the content increases the electrical conductivity of the material also increases. But the high percentage of CNT has adverse effect on the surface finish due to the formation of tangles which cause violent spark and lead to poor dimensional accuracy although the material removal rate was increased. Critical point was addition of 5% CNT after which the electrical conductivity abruptly increases.

Malek *et al.* (2011) studied the effect of conductive phases for machining insulating ceramics and found that the multiwall carbon nanotubes (MWCNT) doped ceramic has approximate three times less tool wear rate as compared to other conductive phase that is TiC. Also the CNT doped ceramic can be machined easily on electric discharge machine with very less vol% addition compare to other material. Discharge energy directly affects the crater dimension of machined surface and also it leads to the degradation of MWCNT due to graphitisation. Material removal rate is almost doubled in case of MWCNT doped ceramic compared to reference material.

Hanaoka *et al.* (2013) has done experimental investigation on electric discharge machining behavior for ceramic composite fabricated by using different carbon nanostructure (MWCNT, graphene). It was found that the density of the ceramic composite is approximately 99% theoretical value and homogenous dispersion was there. Material removal rate was decreasing as the percentage of conductive phase increases in case of electric discharge machining and was also less than assisted electrode machining. Carbonisation of ceramic composite and large chipping area was also observed that depends upon the conductive phase.

Wei *et al.* (2013) optimised the process parameters for electric discharge machining of ceramic matrix composites reinforced with ceramic fiber. The MRR and surface finish increased due to improved flushing and electrode vibration without sacrificing tool wear rate and surface integrity. Peak current and pulse duration are the dominating factors that affect MRR. The mechanism for MRR includes cracking, crack propagation and stripping off.

Li *et al.* (2005) studied and optimised the process parameters for rotary ultrasonic machining of ceramic matrix composites. The reduced cutting force and improved material removal rate can be achieved significantly as compared to diamond drilling process with which high quality holes were made. Material removal rate was greatly affected by feed rate as compared to the other process variables such as ultrasonic power and spindle speed.

Kim *et al.* (2009) performed laser micromachining of CNT/Fe/ Al_2O_3 nanocomposites and found that nanocomposites having high content of CNT produced good machining result and ablation depth of alumina and CNT nanocomposites increase logarithmically with laser influence. No microstructural damaged occurs by laser energy.

Gaps in the Study

Different fabrications methods have been employed for the successful dispersion of the reinforcement and they got positive results and also they find out percolation threshold for machining with electric discharge machining. As the research continues the MWCNT replaces the other electrical conductive phases due to its excellent electrical conductive properties which can be dispersed with conventional methods and by modern methods in ceramic matrix. But on the other hand CNT's are the soft material which can affect the mechanical properties adversely.

Valuable efforts were made in the past to investigate the addition of MWCNT as reinforcement in the ceramic matrix composite in terms of its electrical conductivity, mechanical properties and structural properties. Most of the researchers have fabricated the MWCNT and ceramic with the help of hot pressing, spark plasma sintering and pressure less sintering.

Machining of ceramic is one of the difficult tasks to be performed due to its various mechanical properties which make the ceramic hardest, excellent wear resistant and having high strength material among the various engineering and structural material. Electric discharge machining is the modern machining method which is primarily used for the material having good electrical conductivity. But in case of ceramic as it good insulator so it cannot be machined directly.

Few areas for research have been identified from the above literature review:

Fig. 4 Flow chart for preparation of CMC's and its EDM.

- (1) Fabrication of ceramic matrix composite by using microwave furnace still required to be investigated systematically.
- (2) Although numbers of machining methods are available, each process has its own limitations cannot be directly applied to ceramics or its composites.
- (3) The influence of microwave on the properties of MWCNT's and the ceramic matrix composites.

The scope of this study is limited to the fabrication of ceramic matrix composite by using different percentage of MWCNT with the help of microwave sintering furnace at different temperature followed by evaluation of its electric discharge machining.

Methodology and Planning of Work

Fig. 4 shows the step by step procedure for preparation of CMC's and its EDM.

Case of Relative Density and Porosity

To evaluate the effect of the percentage of MWCNT's on the relative density and porosity of the ceramic composite, one case study is discussed here.

Case Study 1

In this case study, the starting material were used – Al_2O_3 powder (CTC 20, Almatix ACC India Ltd., 99.8% pure, density- 3.92 gm/cm^3), multiwall carbon nanotube (MWCNT) ($>98\%$ purity, outer diameter- 20 nm , density- 2.1 gm/cm^3 , length- $\text{Av } 20 \mu\text{m}$ as described by the supplier). Samples have been prepared by mixing MWCNT's in different weight proportions such as (1, 3, 5 wt%) with the help of ball milling.

Once the milling is over, compaction of the powder is done with the help of compaction press (as shown in **Fig. 4**) at a pressure of 300 MPa . The samples were of circular cross section having diameter 10 mm and thickness of 2 mm (**Fig. 5**).

Fig. 5 Compaction press.

Fig. 6 Microwave sintering furnace.

All the samples were sintered in the microwave furnace (see Fig. 6) at VB ceramics Chennai having magnetron of 2.54 GHz at a temperature of 1500°C for about 15–20 min in inert atmosphere.

Evaluation of porosity and relative density

After the sintering, the samples (see Fig. 7) were tested to evaluate the theoretical density, relative density and porosity of the composites. The porosity was calculated with the help of Archimedes principle. In this first samples were weighted in the air and then in the water. Theoretical densities of the composites were calculated with the help of “rule of mixture” and tabulated in Table 2 and relative density was calculated by the formula given below and the values are as shown in Table 3.

Formulas:

Actual Density = $(m_A / (m_A + m_W)) \times \text{density of distilled water}$.

Fig. 7 Sintered samples of Alumina- MWCNT.

Table 2 Theoretical density of different samples

S.No	Sample number	Alumina (wt%)	MWCNT (wt%)	Theoretical density (g/cm ³)
1	A	100	0	3.92
2	B	99	1	3.9018
3	C	97	3	3.8654
4	D	95	5	3.829

Table 3 Relative density % of different samples

S.No	Sample number	Alumina (wt%)	MWCNT (wt%)	Relative density (%)
1	A	100	0	97.45
2	B	99	1	95.63
3	C	97	3	94.31
4	D	95	5	92.88

Fig. 8 Relation between porosity and MWCNT wt%.

m_A = Mass of sintered sample in air

m_W = Mass of sintered sample in distilled water

Relative density = (Actual density/Theoretical density) $\times$ 100%

Porosity = $\rho_{th} - \rho_c / \rho_{th}$

ρ_{th} = Theoretical density of composite

ρ_c = Actual density of composite

Density of distilled water (liquid) in this case is taken as 1 gm/cm³.

Sintering of samples at 1500°C by using microwave sintering furnace resulted in the improved relative density % of composite containing MWCNT from 0 to 5 wt%. The highest value for relative density was achieved in the composite having MWCNT wt% of

1 and least in the wt% of 5. The decrease in the relative density of the composite with increase in the weight percentage of MWCNT's was due to the poor dispersion of MWCNT's into the matrix phase. On the other hand there was a significant increase in the porosity of the nanocomposites with increased weight percentage as shown on Fig. 7 (Fig. 8).

Conclusion

In this chapter a frame work for EDM of ceramic composite has been proposed. The result of the present work shows the feasibility and development of CNT- ceramic matrix composites by microwave sintering. Moreover, characterization of the developed CNT- ceramic composites (based upon mechanical, electrical and metallurgical properties) needs to be performed before EDM. In order to make the machining of ceramic composites economical the process parametric optimization of EDM for developed CNT- ceramic composites can be explored.

Food Waste for Sustainable Packaging Materials

Valentina Siracusa, University of Catania, Catania, Italy

Introduction

Plastics are considered the materials of the 21st century. During the last 150 years, they have been the key of innovation and have contributed to the development and to the progress of our society. The largest application is in the packaging sector, but thanks to their versatility and high efficiency, plastics have become key materials in many other sectors. Plastics are efficient during the service life, help to avoid food waste and save energy. At the end of their life, they can be re-used, recycled or allowed for energy recovery. In order to guarantee a sustainable development, taking into consideration the fast-growing population, the food security requirements and the climate change problems, the most efficient solution needs to be chosen. Special attention has been recently devoted to chemicals isolated from food waste, coming from food processing industries and considered renewable resources. In this contest, plastics obtained from those resources have been considered as sustainable alternatives to petroleum-derived plastics. Approximately 99% of the plastics produced in the world are obtained from petroleum resources. According to Plastic Europe ([Plastics- The Facts, 2017](#)), from 2015 to 2016 the European plastic production increased from 58 to 60 million tonnes while the world plastic production increased from 322 to 335 million tonnes. Asia (with China and Japan) is the largest producer of plastics (about 50% of the total production), followed by Europe (19%), USA (18%), Middle East Africa (7%) and Latin America (4%). For 2017 and 2018 further increments of +2.5% and +1.5% are estimated. In Europe, the total converter demand is of 49.9 million tonnes, with a demand more than 3000 million tonnes from the six larger European countries such as Germany (24.5%), Italy (14.2%), France (9.6%), Spain (7.7%), United Kingdom (7.7%) and Poland (6.3%). Production, demand and waste management of plastic materials give a great contribution to the world circular economy. Plastics are source of jobs, growth, innovation and sustainability. Plastic is present in several sectors such as healthcare, aerospace, automotive, maritime, construction, electronics, textile, energy generation and packaging. This last one sector is the most important, with a plastic employment of 39.9% of the total demand. Plastic materials and solution were and still are fundamental for the innovative success and growth of such sectors. Plastic materials as well as plastic products are important and efficient resources, along their whole life. At the end of their life they can be reused, recycled or allowed for energy recovery. Unfortunately, due to the large production of plastics materials, there is ever more waste. But wastes could be considered actually as new resources, becoming part of the plastics life cycle. In order to choose the most sustainable solution, several factors such as the plastic waste management, the recycling, the energy recovering considered as complementary option and reducing landfill deposit to the minimum, must be considered. Understanding the life cycle of plastics is fundamental for environmental concerns but not all plastics products are the same. Some plastics present a shelf life of less than one year, some others for more than 15 years and some have a shelf life of 50 years if not even more ([Plastics- The Facts, 2017](#)). For this reason, the volume of wastes does not match with the volume of plastic production and consumption. Between the collected plastic waste, about 27.3% are landfilled, about 31.1% are recycled and about 41.6% are used for energy recovery. Beside in the last ten years the plastic waste recycling has increased by almost 80% and the energy recovery has increased by 61%, plastic litter is omnipresent. Landfill in many countries is still the first option of treatment for waste coming from post-consumer plastic. In Europe only some countries such as Switzerland, Austria, Germany, Netherlands, Sweden, Denmark, Luxembourg, Belgium, Norway and Finland have a landfill rate of plastic wastes less than 10%. For the rest of countries the landfill rate is at 30%–50% and over. The plastic packaging waste is of about 16.7 million tonnes, 20.3% are landfill wastes. For several years, the attention of legislators as well as of public opinion has been focalized on the negative environmental impact of packaging. Its potentiality for food waste reduction and its fundamental role in the product safeguard has been put in a second level. Packaging reduction is consequently seen as the only believable alternative for the environmental impact reduction. But reducing the food waste as well as increasing the food shelf life is in contrast with the final packaging characteristics. Plastics are the most used materials for packaging purpose. They are low cost materials, highly versatile, flexible, transparent, heat sealable, with good thermal, mechanical and barrier performance. But, they are not biodegradable, causing environmental problems not only related to their waste treatment but also because they contribute to the depletion of fossil resources.

So, due to the strong public concern about plastics wastes, a great motivation is driving the development of new materials with strong environmental attributes. Biobased plastics new materials, which could be biodegradable and that could be obtained from renewable resources, are driving this progress. Of course, these polymers could replace synthetic polymers for at least some applications. As reported from [Licciardello \(2017\)](#) and according to [Chen and Patel \(2012\)](#), to [Molina-Besch and Pålsson \(2016\)](#) and according to the definition of European Plastics organization, biopolymers could be obtained from renewable resources (biobased plastics) or could be biodegradable and/or compostable. Consequently, biopolymers obtained from renewable resources could not be biodegradables. As for example, bio-polyethylene (bio-PE) and bio-polyethylene terephthalate (bio-PET) obtained from bio-resources are chemically identical to the conventional ones and consequently are not biodegradable. On the contrary, polymers such as polylactic acid (PLA), polyhydroxyalkanoates (PHAs), polybutylene succinates (PBS) are biodegradable

Fig. 1 Circular economy for sustainable packaging materials coming from food wastes.

polymers, that could be obtained from petroleum resources or from renewable resources. Their biodegradable behavior is related to their chemical structure rather than to their origin (Siracusa and Dalla Rosa, 2018; Siracusa *et al.*, 2008; Peelman *et al.*, 2013).

Very recently, great interest is devoted to the production of polymers starting from monomers obtained from renewable resources coming from agro-industrial and marine wastes and their byproducts. They have been considered as important sustainable alternatives to petroleum-based polymers. A further training force is the consumer's concerns related to food safety, nutritional value and health, that increased the interest to natural substances rather than to the synthetic ones.

In any case, biodegradable or simply bio-based polymers, offers environmental advantages in terms of waste disposal reduction, safeguard of petroleum resources, use of renewable resources coming from the food processing industry that otherwise could become wastes. This process is part of a circular economy, summarized in Fig. 1, followed by retailer and industries to safeguard the environment.

Perpetual disposal in the environment of several food waste, sources of high nutritional compounds and by-product that could be used for several purposes, is a practice that must be stopped. The modern food industry must follow a new strategy for a sustainable bio-economy. Further, the fast growing population, the depletion of food sources, the even more increasing need of high nutritional food and so on is, will be duly this process.

Food Wastes From Industry and Consumers

Every year about 45 billion kg of fresh food such as vegetables, fruits, milk, grain products as well as meat and fish are lost as wastes. Further, fruit and vegetable, olive oil, fermentation, dairy, meat and seafood industries produce a largely quantity of wastes, always related to the food. In order to develop a sustainable food system, food waste treatment technologies as well as food chain management and recovery of high value products from food waste are actually the object of great consideration. A great amount of food wastes comes from retailers, restaurants and consumers and, as reported from Kosseva (2009), every tonne of food waste means 4.5 tonnes of CO₂ emissions in the atmosphere. In the industrialized world, after producing, processing, transporting, sold and take at home, about 33% of food became garbage, and consequently landfilled. In landfill, methane gas is produced, more problematic than CO₂ gas emission. Fresh vegetables, fruits and salad are the major contributors to this process. Further, as reported from Arora *et al.* (2002), vast volumes of aqueous wastes are generated from food-processing industry. Apart from the environmental concerns, such streams represent a great opportunity for the recovery of potentially components that could be used to generate high potential products. These streams include fruit and vegetable residues, molasses and bagasse from sugar refining, bones, flesh and blood from meat and fish processing industries, stillage from wineries, distilleries and breweries, dairy waste such as cheese whey and so on. Wastewaters coming from food industries operation such as washing, blanching and cooling containing also suspended solids and dissolved materials. Actually these products obtained from food industry wastes include animal feed, protein, fermented edible products, yeast coming from bakery products, organic acids, amino acids, enzymes, flavors, pigments, microbial gums, polysaccharides (Joshi, 2002). Despite the great interest confirmed by the numerous scientific patents, articles, book, conferences and so on, the developed technologies remain rather limited. This is because the industrial recovery process is a complex approach that requires careful consideration. A new product can be manufactured and commercialized only if the operating process can be adapted to the existing methodology. This approach requires a certain degree of flexibility, both for the materials than for the technologies just in-use actually. Advantages and disadvantages of the new processing technology must be evaluated, adapting the different approach for the recovery strategy, nature of food waste and the characteristic of the final product.

In order to develop a universal recovery strategy, as reported Galanakis (2015), five-stage recovery approach were described and accepted by the scientific community, that are: a macroscopic pretreatment, macro and micro-molecules separation, extraction, purification and isolation and finally product formation. The conventional technologies must be implemented by following these stages.

Plant Origin	Animal Origin	Fermentation Industry
• Fruits and vegetables (apples, carrots, cherries, corn, grapefruit, pear, peas, tomatoes, mandarine, orange, apple, peach, apricot, banana, kiwi, pineapple and so on) • Cereals (wheat, rye, barely, oat, rice, millet, corn sorghum) • Root and tubers (potatoes, sweet potatoes, cassava, yams, edible aroids, taro) • Oil crops (rapeseed, sunflower, flax, peanuts, sesame) • Pulses (lentil, pea, chickpea, bean, lupin)	• Meat and poultry • Fish and seafood by-products (crab, shrimp, prawn, Antarctic krill, cray fish) • Dairy (whole and skim milk, cream, whey, cheese)	• brewing • distilling • wine manufacture • beer

Fig. 2 Food Waste origination.

Sources of Food Wastes: Challenges for Added-Value Products Recovery

As mentioned before, several food wastes can be taken into consideration for the production of high value added components. The recovery of food by-product for commercial and environmental purpose has inspired the scientific community, to obtain new natural compounds that can be used for the production of bio-based packaging materials as well as for edible films and coatings (Persin *et al.*, 2011; de Moraes Crizel *et al.*, 2016).

First of all, according to the European Union (EU) Commission Council Directive 2008/98/EC, “waste is any substance or object that is discarded”. “Food Waste” instead, according to the Foresight Project reports of the Government Office for Science (Foresight, 2001; Foresight Project, 2011), is defined as “edible material intended for human consumption that is discarded, lost, degraded, or consumed by pets as food travels from harvest to consumers”. Lastly, the European Commission defined the “food waste” as food lost from the food supply chain, without including in this definition the food used as starting materials (monomers) for bio-based products and food for animal feed or used for redistribution (donation). According to the FAO (2014), one-third of worldwide food produced for human consumption are lost or wasted. Thanking into consideration that the objective is to reduce food waste by at least 30% between January 1, 2017 and December 31, 2015 (Otlés *et al.*, 2015), several efforts will be made by all the scientific communities and by industries to reach this goal, for the development of new commercial applications in several sectors such as food, pharmaceutical, biomedical, cosmetics and so on.

It must be considered that food by-products and wastes contain different and complex component with high value. In order to preserve their quality and structure, emerging technology of extraction, purification and characterization are involved.

As reported in Fig. 2, three main groups can be considered for food recovery waste. Each group contains different categories of products that could be considered as sources of different compounds and by-product for new materials production.

For each of these categories, during the industrial and agricultural production and food processing stages, several by-products and waste stream are produced, also containing high value compound. In respect to the food waste recovered at the end of the supply chain, these compounds could be susceptible of deterioration. The waste produced in individual households is instead difficult to recover, and are consequently lost as possible sources of valuable components.

Production of biodegradable packaging material as well as edible films and coatings for food packaging application is grown quickly due to the public attention for environmental problems. These new materials could be a great alternative to synthetic packaging materials in several application, thank to their capacity to prevent loss of aroma, moisture, gas penetration, water absorption and so on (Cazón *et al.*, 2017). Mainly proteins (including collagen, casein, fish gelatin, quinoa protein, whey protein, corn zein, wheat gluten, egg white protein, soy protein, keratin protein), lipids (including waxes, acylglycerols, fatty acids) and polysaccharides have been used to produce biodegradable and edible films. Chitosan starch, pectin, alginate, carrageenan, pullulan and kefiran are interesting candidates for film production (Elsabee and Abdou, 2013; Galus and Kadzińska, 2015). In the majority of cases, their properties have to be improved and the use of different plasticizers is required. The use of natural plasticizer, like triglycerides from vegetable oils and fatty acid esters (Veira *et al.*, 2011) are of course of great interest in order to respect the environmental attributes of the synthesized materials. Alginate and carrageenan films are highly hygroscopic and can be used as thin films on the surface of food to absorb water and protecting the food moisture loss.

Food Waste From Plant

Fruit and vegetable wastes

As reported from Mullen *et al.* (2015), depending on the fruit and vegetables processing technologies, several type of wastes and by-product are produced:

1. Solid wastes such as pomace, pulp, peels, cores, seeds, stems,
2. Liquid wastes such as juices, wash water, chilling water, cleaning chemical water.

Since these wastes are rich in biologically substances, the use of fruit and vegetables by-product as a source of active and functional compounds is a very interesting technological and environmental tool. These types of wastes are produced in large

amount and also constitute a source of municipal solid compost wastes because of their high biodegradability (Misi and Foster, 2002). The waste coming from fruits and vegetables processing industries contains large amount of suspended solid (SS). The organic fraction is formed by about 75% of sugar and hemicellulose, 9% of cellulose and 5% of lignin. In practice, these wastes are made in major measure of hydrocarbons and small amount of proteins and fat, with moisture content of about 80%–90%. In general is difficult to use the wastewater stream because it contains a high amount of dissolved compound such as pesticides, herbicides and cleaning chemicals.

Of course the best solution for a green and environmental production is to reduce drastically the waste production but this is not possible at all, so the actual interest is to valorize by-products and residues of the fruit and vegetables processing technology. Several approaches are followed such as the extraction of flavors, dietary fibers for bread and beverages, pectin and gelling agents to be used firstly in the food sector as well as in others such as for animals food, cosmetic and so on. The advantage of course will be economical (resources preservation, niche market with high profits, reduced cost for waste disposal) and of course for the environment.

One of the most interesting and studied, low cost and abundant fruit byproduct is the apple pomace, formed by peel, core, calyx, stem and soft tissue, with high water content and insoluble carbohydrate such as cellulose, hemicellulose and lignin. Also sugars (glucose, fructose, sucrose), minerals, proteins and vitamins are present (Kosseva, 2009). The most important biotechnological application of apple pomace is the production of enzymes, aroma compound, ethanol, organic acid, polysaccharides, baker's yeast and pigments. Vendruscolo *et al.* (2008) reviewed all the bibliography regarding this product, its transformation in high value added compounds and their use for emerging technologies. The utilization of this product is important not only because it is a low-cost resource but also because it is a resolution of the pollution problem due to the high amount of wastes disposal. The most important application is the production of enzymes that could be used for food application as well other sectors such as textile. As reported from Hofvendahl and Hahn-Hagerdal (2000), apple pomace could be used to produce lactic acid by enzymatic hydrolysis. Taking into consideration that the world market is growing and that its current production is at about 150 million lb for year, the possibility to use food waste renewable resources is of great interest. Biodegradable polymer polylactic acid (PLA), obtained from the polymerization of lactic acid, is actually one of the most used as food packaging. Its behavior was just fully investigated (Siracusa *et al.*, 2012, 2017; Siracusa and Ingrao, 2016). As reported from Kosseva (2009), from apple pomace is possible to obtain high level of glucose and fructose, excellent carbon sources for lactic acid production, high level of cellulose, starch, hemicellulose that can be hydrolysed to produce monosaccharides and that could be used to produce starch derived polymers.

Cazón *et al.* (2017) in their review reported the possibility of producing biodegradable film and coating coming from polysaccharide. Not only apple pomace was investigated but also orange and lemon pomace as well as peels of several fruits such as orange, lemon, pear, banana and melon. From apple and citrus peel is possible to obtain pectin, one of the main components of plant cells. Its structure is strictly related to the microstructure. The carboxylic groups can be esterified with methanol, obtaining several rate of esterified carboxyl groups (>50%, high methoxyl pectin; <50%, low methoxyl pectin), related also to the molecular weight. These parameters are important for other properties such as gelling, texture and stability, important for the future film production. Pectin-based films show good gas permeability properties, poor water barrier behavior, retard in moisture loss and lipids migration (Gutiérrez-Pacheco *et al.*, 2016).

Taking into consideration the high cost of aromas, fragrances and flavors compound production from raw materials such as plants and considering the high cost of the used technology on an industrial scale, there is a great interest on low cost processes using food wastes resources.

Iahnke *et al.* (2015) reported the preparation technique of a gelatin film obtained from linseed oil and carrots, both coming from processing industries wastes. This film was tested as sunflower oil package and was found that the presence of carotenoids protected the oil from the natural oxidation process.

Cereals wastes

In this category are comprised nine species of Gramineae family, that are wheat, rye, barely, oat, rice, millet, corn, sorghum and triticale (Mullen *et al.*, 2015), that represent the most important source of food for human and meat preparation. They are an important source of several compounds such as carbohydrate, proteins, lipid and vitamins. The process followed to obtain refined products (dry milling, pearling, malting) such as white bread, pasta, white rice and so on give a great portion of wastes with high concentration of bioactive compounds. In general, those compounds are used as reinforcement for biodegradable materials, especially in order to improve their mechanical and barrier properties, fundamental characteristics for the packaging sector. Straw coming from the processing of wheat, rice and corn, consists principally in cellulose, hemicellulose, lignin, ash and protein, and is the most abundant lignocellulosic biomass. Wheat mill, rice mill, oat mill, barely mill are all reach of antioxidant, hypocholesterolemic, anticancer and antitumor compounds. They are also used as ingredients for animal feed. As reported from several authors (Aider, 2010; Elsabee and Abdou, 2013; Jiménez *et al.*, 2012; Psomiadou *et al.*, 1996) polysaccharide based films have low cost, is available and specific properties. They present good barrier properties against gas such as O₂ and CO₂ that is an important property to avoid oxidation and ripening of packed food. Further, it is important to retard the loss of organic vapours (aroma compounds) during storage and to prevent external contamination and food quality loss. But, being hydrophilic, they show poor water vapor barrier properties that could be improved with other functional substances.

Cellulose is the most abundant component coming from renewable resources. It is low cost, non-toxic, biocompatible, biodegradable and chemically stable. It can be isolated from plants and it is the most common choice as filler for plastic materials (Kolybaba *et al.*, 2006). It is insoluble in polar solvent such as water, due to the high length of the cellulose molecular chain and due to its high crystallinity. As it is a very important raw material for biodegradable film production, their solubility in no-chemical

solvent is under study in order to guarantee the environmental attribute. The films obtained are transparent, water soluble, odourless, tasteless, flexible, with moderate strength and resistance to lipid environment (Dhall, 2013; Baldwin *et al.*, 1996).

Starch is a natural polymer and a good alternative to be used for produce packaging material. It is abundant, low cost, biodegradable and edible. It is present in different plants such as wheat, corn, rice, bean and potatoes. The shape, size, structure and chemical composition varies depending on the source. The two main polysaccharides present in starch are amylose and amylopectin. Lipid and protein are also present. Amylose is a linear polymer responsible for the film forming properties while amylopectin is a highly branched polymer. The amylose/amylopectin ratio is responsible for the crystalline structure. The crystalline region is associated with the short-branched chains of amylopectin meanwhile the amylose is associated with the amorphous region. The film could be obtained by two techniques: dry process and wet process. In the dry process, the starch is plasticized and heated above its glass transition temperature and then extruded. In the wet process the polymer is solubilized and the film is formed after solvent evaporation. This last process, is preferred for edible film forming or coating obtained by dipping, brushing and spraying onto the food surface. The first method is preferred at industrial level (Peressini *et al.*, 2003; Jiménez *et al.*, 2012). The films are brittle due to the amorphous regions formed by amylose. To overcome this problem, plasticizer could be used, improving flexibility and extensibility. Another possibility could be to blend the starch with other biodegradable polymers in order to maintain its biodegradability while improving the mechanical properties (Cazón *et al.*, 2017).

Roots and tubers wastes

Roots and tuber crops are potatoes, sweet potatoes, cassava (manioc, mandioca, yucca), yams, edible aroids (malanga, new cocoyam, acumo, tannia), taro (dasheen, eddoe, old cocoyam). Cassava, potato and sweet potato are the most produced for human consumption. About 55% of the total production is used for human food, while the rest is used for animal feed or for producing starch, distilled spirits, alcohol. They represent the second rate wastes after fruit and vegetables.

The waste and by-products coming from potato processing industry comprise peels, cutting waste, wastewaters, pulp and liquor after potato starch processing, scraps (broken fried chips and so on). From peels is obtained the great amount of carbohydrates, followed by protein, moisture, ash and sugar. Phenolic compounds (chlorogenic acid, gallic acid, caffeic, p-coumarin, ferulic, vanillic) are present in potato peel and can be used as antioxidant agents for active packaging materials. From potato peel can be extracted dietary fiber and it is an excellent substrate for the production of bioethanol.

Cassava, the major root crop used in developing countries such as Nigeria, Thailand, India, Indonesia, Bolivia, and so on, is used as primary food but also to manufacture starch and bioethanol (Padmaja and Jyothi, 2012). The wastes obtained during processing are made of starch residues (pomace) used for the production of bioethanol and lactic acid (Ray *et al.*, 2008), peels, stumps, whey and wastewaters.

Oil crops and pulses

The most oilseed groups cultivated for oil production are olive, rapeseed, sunflower, flax, peanuts, sesame. In general the oilseed processing includes several stages such as cleaning, dehulling, cooking and oil extraction. Each stage generates several types of wastes that could be recovered. Stems, pods, leaves, broken grain, dirt, small stones are obtained. Waste of oil production, coming from industrial processing, is a dark-colored juice, with organic substances such as sugar, organic acids, polyalcohol, pectin, colloids, tannin and lipids (Kosseva, 2009). As reported from Galanakis (2015), the first success on the food waste treatment was the recovery of oil from the olive kernel, inspiring the scientific community to intensify their research toward the valorization of such and similar by-product.

Pulses are the second most important kind of food in the World. It is rich in protein and others nutrients such as carbohydrates, dietary fiber, vitamins and minerals. Their by-products are used for bioethanol production and for biodegradable and edible films (Mullen *et al.*, 2015; Del Campo *et al.*, 2006).

Recently the production of edible films and biodegradable polymers has been the object of several studies from researcher, by utilization of proteins, polysaccharides and lipids coming from such type of wastes. Protein films show great mechanical performances, better than the films obtained from lipid or polysaccharides starting materials (Mariniello *et al.*, 2003). As reported from Mullen *et al.* (2015), pulse and oilseed by-product are suitable materials for the synthesis of films. Soy protein, among the other plant protein sources, gives flexible, smoother and clear biodegradable polymer films. By combining different type of polymers with different origin (composite films) is possible to mix several characteristics, giving rise to films with improved properties in respect to a single polymer. Salmoral *et al.* (2000a,b) described polymer films obtained from bean protein, using starch glycerol as plasticizer. Garrido *et al.* (2013) reported their study focalized on the preparation of soy protein thin films, obtained by casting and compression methods. Optical, barrier and mechanical properties were found to be influenced by the processing procedure, due to the changes observed in their structure during film forming. By casting method were obtained films with better flexibility and transparency, lower yellowish color and gloss and higher resistance against water. By extrusion instead the properties were influenced by the temperature used to press the films. Garrido *et al.* (2014) reported their study on biodegradable films obtained from soy coming from waste of soy oil industry. Was analyzed the effect of plasticizer content on the best formulation, processing condition and functional properties of the final films as well as their structural change.

de Moraes Crizel *et al.* (2018) reported their study on the production of chitosan based films with the addition of several percentage of flour and microparticles of olive pomace flour. The obtained film, studied from mechanical, barrier, optical and antioxidant properties point of view, showed good performance. The films were tested on the oxidation rate of nuts, during 31 days of storage.

Food Waste From Animal

Meat and poultry

Meat industry produces a great amount of wastes coming especially from the slaughterhouses and processing units. In particular blood, fats, intestine, paunch grass, manure are the principal residues (Cournoyer, 1996). The wastewater streams are rich of moisture, phosphorus, nitrogen and pathogens that must be eliminated, and is always more difficult to treat in respect to the solid food wastes. From meat residues is possible to isolate collagen, that could be used to produce edible films with excellent mechanical properties (Osburn, 2002). In the packaging sectors, films and foils obtained from meat protein hydrogels present high barrier behavior for oxygen (to avoid food oxidation), carbon dioxide (important for modified atmosphere packaging technology for preserve fruits and vegetables), and aromas (for finished food products). The disadvantage is their lower moisture barrier capacity due to the hydrophilic character and high water solubility, coming from their natural origin. Further, the mechanical behavior is lower (mechanical strength and elongation at break) with high fragility compared to the synthetic polymers used in the same field. This negative effect could be controlled by adding suitable plasticizer that could however increase the hydrophilic character and consequently reduce further their moisture barrier capacity. The hydrophilic character can be modulated by crosslinking reaction with specific enzymes or aldehydes.

Collagen protein, obtained from enzymatic hydrolysis of meat wastes, can produce hydrogels applicable for the synthesis of biodegradable packaging materials to be used in food, cosmetic and pharmaceutical sectors (Kosseva, 2009). Thank to this procedure, as reported from Langmaier *et al.* (2008), the ammonia pollution of wastewaters coming from collagen processing technology, as well as the collagen solid wastes in landfills could be avoided, with a great advantage for the environment.

Fish and seafood by-products

In general, about 25%–30% of the total fish and seafood weight became waste. Waste generated from fishing, aquaculture, and fish processing industries are the most important environmental problems in the coastline areas. Generally fish and seafood wastes are dumped into the sea, without any kind of treatment. They are of course lost without any possibility of valorization. The shellfish industry produces a great amount of crustacean waste materials. The most harvested species are crab, shrimp, prawn, Antarctic krill, cray fish. The use of such crustacean wastes is of great interest by researchers because they are very rich in protein, chitin, chitosan and carotenoids. Chitin is the most abundant natural polymer in the World (Santhosh and Mathew, 2008) and is obtained from shrimp shell waste. Thank to their low toxicity and higher biocompatibility, it is used in medicine, cosmetics, textiles, food and so on. Glucosamine and carboxymethylchitin are two of the main derivatives of chitin.

From alkaline N-deacetylation of chitin is obtained chitosan. It is commercially available from renewable resources such as waste coming from shell-fish industry (Kim *et al.*, 2006). It is a linear polysaccharide, non toxic, biodegradable and biocompatible, with high antimicrobial activity. The films could be obtained by several procedures. One of them is by casting method, where chitosan is dissolved in a suitable solvent, with the possibility to add plasticizers. The solution is poured on a flat surface and the solvent allowed to evaporation. Of course, this could not be used as commercial procedure. Extrusion instead could be the most economical procedure when foils have to be obtained. But chitosan degrade before its melting point and therefore cannot be extruded or molded and the film cannot be heat-sealed. To overcome this problem, chitosan is blended with other natural polymers such as poly(butylene succinate), poly(butylene succinate adipate) in order to improve the thermal properties (van der Broek *et al.*, 2015). The films obtained show good mechanical properties and permeability to CO₂ and O₂. Due to its high water permeability its use is limited, especially in high relative humidity environment, in the case where an effective moisture control is required for avoid quality and safety food loss. For this reason several strategies have been studied such as the plasticization or mixing with other component such as protein or polysaccharides.

Tuna is the most favorite fish species and its processing to produce different tonnes of skin, bone and fin as food wastes, used for fish-feed or fertilizers. In order to reduce the fish processing waste cost and the management and disposal waste cost, the interest for those wastes is increased. They can be used for enzyme, protein, collagen and gelatin recovery (Klomklao *et al.*, 2005; Slizyte *et al.*, 2005; Fernandez-Díaz *et al.*, 2001; Muyonga *et al.*, 2004a,b; Choi and Regenstein, 2000).

From wastewaters coming from the industrial processing of octopus, several groups of peptones could be obtained through enzymatic hydrolysis, promoting the growth of lactic acid bacteria. From industrial point of view, such bacteria are the most important for the production of lactic and acetic acid, ethanol, diacetyl and 2,3-butanediol molecules, that could be used as monomer for future polymerization processes (Kosseva, 2009).

Ettxabide *et al.* (2016) reported their study on fish gelatin films obtained from food wastes, obtained by solution casting with solution of different pH value. Mechanical, barrier and optical properties were evaluated as well as their environmental impact by Life Cycle Analysis technology.

Dairy

The dairy industry covers a great part of the food industry and consequently the production of waste is really consistent. The demand for milk and dairy products is still increasing, especially in Europe and North America. They contain principally fatty acids, lactose and suspended solids. The wastewater may contain proteins, salt, fatty substances, lactose and cleaning chemicals (Kosseva *et al.*, 2003). The wastewater streams are difficult to treat due to the high concentration of detergents, surfactants, like polyphosphates, EDTA, that remain after treatment and that is problematic for the ecosystems of rivers because their toxicity for aquatic animals (Thassitou and Arvanitoyannis, 2001).

Etxabide et al. (2017) in their review, fully described gelatin film obtained from bovine food waste (but also from porcine and fish), to be used for producing active packaging. The incorporation of natural antioxidant and antimicrobials into films can be seen as a tool to extend the food shelf-life, reducing food losses.

Wastes From Fermentation Industry

Liquid wastes produced from the fermentation industry are similar and contain many common compounds such as tannins, phenols and organic acid. These streams are difficult to treat.

Grape pomace, consisting of skins, seeds and stalks, coming from wine production, could be used to produce aroma compounds. But, the chemical composition is very complex because alcohol, acids, aldehydes, esters, pectin, polyphenols, mineral substances, sugar and other chemicals are present (*Torres et al., 2002*). Grape pomace is used also for ethanol distillation, which could be used as bio-resource of monomers for the production of bio-polyesters.

From brewing industry, a great amount of brewers' spent grain is obtained, used principally in animal feed thanks to the high protein and fiber content. It is also rich in bioactive compound such as phenolic acid and other chemical components (*Peterson and Qureshi, 1993; Sz wajgier et al., 2010*).

Future trends

Environmental concerns about the even more large quantities of food wastes produced in the World have generated a great interest versus new and alternative technologies, environmental friendly. These wastes could be used as substrates for producing chemicals with great economic value. First of all, microorganisms coming from these wastes may be important because capable of converting such materials into valuable products. Industrially, at the moment, in this area much more has to be done, for reaching a technological and economic feasibility.

The use of vegetable wastes can contribute to a reduction in the use of raw materials as well as in the waste minimization production.

Fruit and vegetable processing is used to obtain by products with high functional attributes is important to reach. For this, much research is still need in order to found the best food processing technology, in order to develop the best method for a complete utilization of by-products coming from food wastes, to reduce the presence of toxins and to assess the bioactivity and toxicology of such new chemicals. Functional food is an important area of the food market. However, if obtained from food waste by-products, the potential risks must be carefully controlled. Their stability and interaction with other food during processing as well as during storage must be fully investigated.

Starch based industrial wastes are important substrates for the production of polyhydroxybutyrate polymers (PHBs), contribution not only in the reduction of the sludge landfilled but also in the reduction of the cost for their synthetic production.

The mechanical as well as the barrier properties of biodegradable polymers and edible films coming from food wastes products are away from properties of the most common synthetic plastics used in packaging. They have been improved by combining each other several polymers but further research has to be enhanced. Of course, the goal is to obtain biodegradable polymers with properties much more similar to commercial ones. Probably in a near future these polymers will be a good alternative to replace the synthetic ones, more economic and commercialized.

The production of biogas is also viewed as a great new opportunity for energy natural recovery. As an example, the anaerobic digestion of the fruit and vegetables waste is a commercially process to obtain methane gas. Production of hydrogen from dairy waste effluent is currently worth investigating.

While the anaerobic technologies are simple and low cost for producing biogas, aerobic technologies are still highly energy intensive and still require more research to adapt them to the economic World concept.

In order to well understand the environmental impact of the new funding the most important tool is the Life Cycle Assessment (LCA) analysis technology (*Leceta et al., 2014*). Thank to this approach, it is possible to understand and identify the steps that in the food chain have the largest impact, in order to target the improvement efforts. It is important to choose the correct raw material, packing system, as well as all the input use for choosing the best waste management strategy. Adapting the LCA technique to the social value, as well as to the ethical and moral value recognized from the World, is the future step in the development of the correct food waste management.

Conclusions

The increasing interest versus high-quality food products and the increasing interest versus the environmental preservation encouraged the researchers to develop new edible films as well as biodegradable films and coating, to be used in the food packaging sector. For their production, renewable resources could be used and among them, food waste resources are gaining even much more interest in the scientific and industrial world. Edible films are used to preserve food from its surrounding, and could be obtained from biopolymers hydrocolloids (such as gelatin, keratin, collagen casein, soy protein, whey protein, wheat gluten, corn zein, starch, cellulose, plant gums), lipids (such as waxes, acylglycerol, fatty acids), resins (such as shellac and wood resin) and composites (lipid and hydrocolloids). In general they are obtained by thermoplastic processing technology (extrusion and

compression molding), commercial processing with high potentiality for the large-scale production. In order to avoid facilitating the processability avoiding deformation and thermal degradation and to undergo the glass transition temperature, natural additives such as glycerol, sorbitol, sucrose, water and other plasticizers could be used.

Films packaging obtained from food waste and used as wraps, pouches, bags, casings and sachets for food protection, requires a full base characterization in terms of mechanical, thermal, barriers and microstructure, as well as the possibility of their recyclability.

The development of such new environmentally products must come from an interdisciplinary activity. Integration between market, research, manufacturers, consumers and society is fundamental for pollution control and waste management, for the reduction of the environmental contamination. The innovation must be obviously focused on consumer needs but without losing the respect for the environment. Unfortunately, some recent developments consider the public demand more important than the respect to sustainable resource utilization. So, the current trend in the development of a new product and technology is to consider the quality perceived from the consumer as the starting point and, around this, build the future. Market orientation is fundamental for the success of an innovation, especially for the food sector. In the food market three strategies are fundamental for development that considers the increase of bioenergy demand, the decrease of water consumption and natural resources. Without innovation, consumers' needs cannot be affordable. Innovative packaging and processing technology are two answers to be addressed in order to reach such innovation and to provide better opportunities for consumers.

Introduction

Based on the thorough fundamental analysis of relevant literature and actual cases, the main characteristics that need to be taken into consideration when planning the implementation of integrated software solutions in a project are presented in this paper. Market ERP on supply and demand is segmented to systems for small, medium, and large enterprises (**Fig. 1**) (**Denić, 2010**). The division is not only dictated by annual revenues, the number of employees, and other parameters, but also the speed and extent of changes in the process of the business itself. **Fig. 1** outlines the largest and most successful vendors of software applications throughout the world (**Denic et al., 2013a**). As each vendor achieved success with their first application, they developed other applications for other business processes or united existing applications. Successful vendors have software applications for almost all major business processes, in which all applications are assembled into one product and which is called enterprise resource planning ERP or integrated information systems.

ERP Facts

The actual state of ERP systems has been to initiate more and more specialists to deal with current issues and points of great importance, characteristics and the performance of the ERP system. **Roger Rigelhof (2003)** describe the reasons why ERP systems are a special type of information system:

- In their design, ERP systems have the widest use of all organizational information systems and software packages – they are used in all functional areas and at all levels of organization.
- ERP systems present an advantage as they are constructed in the manner that most organizations use information systems. ERP systems are complex systems; they are not used separately in extremely large organizations or are only used in certain industries.
- Due to their complexity and the fact that an organization's success is dependent on the rapid response of these systems, they have sophisticated skills and experts in the implementation process; therefore, the introduction of ERP systems are one of the most sought-after professions today.

All ERP systems are based on (**Dahlen and Elfsson, 1999**):

- Data (the information required for business),
- The integration of data (processing and transport),
- Functionality (collection, storage, and display-transfer).

Table 1 presents the successful implementation where 5 of 9 listed companies carried out the implementation of SAP.

Fig. 1 Market share of ERP applications. Reproduced from Chorafas, D.N., 2001. Integrating ERP, CRM, Supply Chain Management, and Smart Materials, str.77. Exhibit 6.3.

Table 1 ERP successes derived from literature review

Organization	Industry	Implementation scope	Why success?
Earth Grains	Bakery products (USA)	SAP's R/3	The project started with the clear strategy and each department had analyst reporting issues to management. Change compensation system to employees after implementation. Involved interpersonal skills for training and strong knowledge on technical and the company business process.
Monsanto	Chemical and life sciences	SAP	Success factors in Monsanto project dealt with the management structure, the redesign of business process, and investment in re-skilling by proving training, and acquisition of external expertise.
U.S. Mint	Coin production	PeopleSoft \$40 million	The project started with a business requirement. Employers were able to see how everything needed to be coordinated. People received training in the use of the system and used of external consultant on the project. The Project also involved Senior management and organizations understand that the undertaken project will be painful and expensive but expected to provide savings of \$80 million over the next seven years.
Ralston Purina	Manufacturing	Oracle	The CSF for Oracle project at Ralston included Strong management support, experienced technical consultants and project manager and effective user training.
Sigma Chemical	Chemical industry	SAP	Support from top management, BPR, Invest in training and re-skilling and used of consultants.
Scripps Metabolic Clinic	Multi specialty medical group and clinical research institution.	Lawson ERP integrated solution on HP 9000	Reliable vendor partnership and successful system integration.
Houston Independent School District	Public sector and education	SAP ERP modules	Project started with well plan BPR and focused on the integrating legacy system and an existing PeopleSoft Inc. Selected a right team also become part of success factor. The system already has shown a 42% return on investment and has lowered inventory by \$1M.
Experience Point	Manufacturers of aircraft	Not provided	The project started with the used of external consultant. Manage to get top management support and user participation. The company also provided training to the user in order to improve their understanding towards the system.
Anheuser Busch	Manufacturer of Beer and related food product	SAP	Provided a cost savings based upon integration of data and processes, a common database, and increase leverage of purchasing and buying. The critical success of the implementation included used of external consultants, project champion, BPR, top management support, technical and business knowledge.

ERP Implementation

Some of the factors the ERP system and the implementation of integrated information systems are here presented below. Other well-known experts and authorities on the ERP system highlight the peculiarities and specificities of these systems, such as the authors [Skok and Legge \(2001\)](#) who point out that ERP systems are often seen as the new paradigm for the development of information systems, due to the following factors that differentiate them and make them recognizable:

- The number and diversity of investors in any implementation project,
- High cost implementation and consultation,
- Integration of business functions,
- Resultant software configurations that represent basic processes,
- Change management and policy issues related to BPR (Business Process Reengineering) projects,
- Commitment to education and training needed for familiarization.

ERP can be described by five basic facts ([Wallace and Kremzar, 2001](#)):

- A wide range of tools that align supply and demand,
- Connecting buyers and suppliers in a unique value chain (a value chain represents the activities of individual steps through which all services or products the company achieves added value),
- The efficiency of a company is reflected by its adopted business decisions,
- Inter-linking sales, marketing, manufacturing, logistics, finance, and human resources development,
- A common goal is a high level of productivity and low cost.

Some of the most important guidelines in the process of introducing modern sophisticated information systems are here presented below. It is very important that when implementing ERP systems or the introduction of a new information system to pay special attention to cooperation bidder and suppliers who aim to achieve a partnership (Denic *et al.*, 2014). This allows both parties to achieve their goals. On the one hand, an important role is played by the personnel structure of suppliers, which reduces associated human factor risks; however, the supplier is also a bidder of solutions tested in practice due to their knowledge introduced in the company (Roger Rigelhof, 2003). One of the largest manufacturers of sophisticated ERP in the world is SAP, who recommend that their customers compose design teams be led by a project manager, which corresponds to the executive and steering committee, formed by experts of SAP (functional analysts and leaders of functional teams) and a SAP associate partner – the leader of the technical team, technical analysts, and system administrators (Larocca, 1999). A very important role in the introduction and implementation of ERP systems is to have users who know the needs of introducing a software solution. This, however, does not constitute the user's request, since the requirements are not clearly defined. At the beginning it is necessary to predict the (Roger Rigelhof, 2003):

- The details of the work,
- Changes in circumstances in which the program is running,
- Usage,
- The availability and accessibility of the system,
- The criteria for accepting or rejecting changes,
- Response time and time frames the possibility of changing requirements,
- A method to document changes that are usually associated with additional costs.

The last phase in introducing the ERP system is the actual implementation of information systems, setting up the network, the installation of personal computers, user training, and data migration to the new system. The technical team shall perform the following tasks (Bancroft, 1996):

- Construct the network infrastructure,
- Install shortcuts,
- Train and support users,
- Communicate,
- Enter the correct data in production system,
- Start the system.

The reasons for the implementation of ERP systems in Serbia, the United States, and Sweden can be seen in Table 2.

It is evident from Table 2 that the reasons for the implementation and introduction of sophisticated ERP systems generally coincide, regardless of the geographical area of the companies. However, some discrepancies in the values show that there are some specifics in business and business systems in developed economies of the world and companies in the Western Balkans (Denic *et al.*, 2013b). The following Fig. 2 shows the use of ERP solutions in Serbia.

To study the global market, in addition to the relevant literature used, sources from Gartner, a leader in providing information on the state of the market in the field of ERP services have been examined. To study the local market, one of the sources is self-attained experience in this area, where many years of active work have been reflected in numerous surveys that have been conducted in several hundred major IT companies in Serbia, which is the basis for thoroughness of the research. Business systems and enterprises in Serbia usually implement modules related to finance and accounting, human resources, sales, and distribution (Denic *et al.*, 2013a). Less commonly implemented modules are those that are related to product lifecycle management and advanced planning, as well as supply chain management. The implemented ERP solutions of Serbian manufacturers are presented in Fig. 3.

Table 2 Comparative reasons for implementing ERP solutions

Reasons for implementing ERP systems	Serbia		United States		Sweden	
	Important	Rank	Important	Rank	Important	Rank
Replacing old (legacy systems)	4,39	1	4,06	1	4,11	1
Simplification and standardization of systems	4,07	2	3,85	2	3,67	2
Improving interaction with suppliers and customers	3,97	3	3,55	3	3,16	4
Gaining strategic advantages	3,90	4	3,46	4	3,18	3
Pressure to keep up with the competition	3,85	5	2,99	7	2,48	8–9
Integration into global activities	3,78	6	3,17	5	2,85	6
Restructuring the organization	3,54	7	2,58	9	2,70	7

The IT market in Serbia and in the Balkans (Fig. 4) has made progress in the previous decade, but not yet enough. In order for the economy and society to emerge out of its crises of the last two decades, it is essential that IT investments in Serbia double every 5 years (15% yoy). Investment is off to a good start. From 2005–2008, the market doubled, but from 2009 to 2011, IT investments deteriorated, so much so that the average annual growth rate for the years 2005–2011 fell below 10% (Enterprise Research, 2014).

Really high growth rates are needed for a modest state in the year 2020 (Fig. 5).

The potential IT market in Serbia is much higher than what has been achieved in recent years. The potential is great, but is currently unable to go even higher. If Serbian ERP investment cannot be duplicated in the next five years, Serbia's economy and society will fall even deeper into a crisis (Fig. 6) (Enterprise Research, 2014). The ERP market has plenty of room for growth. Typically, 10% of the ERP market in Serbia is about 7% (Fig. 7). However, it is necessary to be careful with personnel who are increasingly being outsourced (Enterprise Research, 2014).

According to percentages, 15% of small enterprises (10–49 employees) 1522/10,000, 30% of medium-sized companies (50–249 employees) 308/500, 60% of large companies (250–999 employees) 308/500, 100% of very large companies and systems (greater than 1000) 75/75 (Fig. 8) (Enterprise Research, 2014).

Conclusion

In a research paper is presented to the importance of the success of the introduction of an information system in Serbia. ERP solutions on the market today, more or less successfully cover core business processes and enable the efficient governance of enterprise resources. However, the specificity is mastering the business processes that the company provides a competitive advantage. The world's leading ERP packages are technologically modern, integrated and represent reliable software support. The

quality of built-in software support, however, is surprisingly good. Customization and implementation of the ERP solutions can take from six months to two years or more, resulting in a wide range of product prices and the cost of customization specific to the customer's needs. The main reason for the high cost of an information system that is being built in this manner, is the need for simultaneous adaptation of software solution to the organization and adapting of the organization and its business processes to the software solution. The very use of the software in the enterprise does not have any problems, such as meeting the needs for normal operation. So far we have not had the need to the required analysis, justified by its small size and management by financial owners. Also modern sophisticated ERP solutions offer many possibilities, but these possibilities and benefits are not used in a good deal of business entities and companies in Serbia and the region, some because of their small size, but in most cases also due to lack of knowledge of positive impact of business intelligence or technology for business decision making.

During the global economic crisis in 2008, when it covered the global market, many companies in the region experienced a smaller decline in business only during the period of three months, just because of new clients situation has improved as it was. Source of given data is useful, the only question is whether management had an interest for such changes.

High Dynamic Range Imaging and its Use in Daylight and Lighting Design

Anne Gorman and Antonello Durante, Technological University Dublin, Dublin, Ireland

© 2020 Elsevier Inc. All rights reserved.

Introduction

There are many metrics in use today that will measure a variety of aspects of daylight and artificial lighting. The aim is to determine adequacy and consistency of light levels including the absence of glare for visual tasks in the built environment. The focus historically has been “ensuring a consistent level of light was achieved over large areas” (Cuttle, 2010). There has been, until recent years, a focus on “illuminance regardless of the direction of the incidence of light on a horizontal, 2-dimensional plane” (Cuttle, 2010).

Following on from this, the focus has turned to one of human need for lighting and the idea of visual performance. However, the predominant measuring of illuminance, which has no visual effect, is disconnected from what the viewer sees (Cuttle, 2010).

Few, if any, metric measures exactly what is actually seen by the human eye. It is not possible to relate these metrics to, or to capture the light levels from, the visual scene entering the eye. In recent years the development of affordable digital single-lens reflex (DSLR) digital cameras has given rise to the use of high definition range imaging (HDRI) as a means of making this important connection.

In photography, the term *dynamic range* usually represents the ratio between luminance values spread across the spectrum of darkness to brightness. The human visual system can easily adapt to visual scenes within the range of 10 orders of magnitude for a single scene, and its range overall is 1,000,000–0.0000001.

Widespread technological instruments currently used for imaging such as LDCs and regular cameras are not capable of capturing the full dynamic range of scenes in a single exposure that can be seen from the human eye in real life. This is due to the properties of the photo sensor within the camera that converts photons to electrons (Jacobs, 2007).

A small number of professional instruments capable of capturing, in a single shot, the dynamic range that humans perceive are being developed, but effective and affordable solutions are still rare (Jacobs, 2007).

One solution to this problem is represented by the HDRI technique. The HDRI is an image processing technique that allows the capture of a greater dynamic range of exposure than normal low dynamic range (LDR) technology. It is based on combining multiple images with different exposures (ranged between low exposure value images to high exposure value images) to create a single image that captures the full dynamic range. From this HDR image containing light data a measurable luminance map can be produced.

Over spot luminance meters, this technique has the ability to capture luminance in the human field of view more rapidly and with a higher resolution.

The accuracy of luminance measurement with HDR photography is widely influenced by the care taken during acquisition and treatment. A measurement error of less than 10% can be expected (Cauwerts and Pederit, 2018).

A Brief History of HDR

The first time cameras were used as measuring tools to capture photometric measurements was in the early 1960s. In the mid-1970s, photographic instruments were used to measure the luminance distribution in the sky vault. This was the start of a number of research groups setting up systems to analyze sky luminance. The most significant collaboration of research groups in this area, SERI-LM23 was set up in 1984 and included the Solar Energy Research Institute. Their system developed to be a basis for sky models and covered a luminance range between 200 and 16,000 cd/m² with a field view of pi steradians (Bellia and Spada, 2014).

These systems had difficulties as a result of the limited range of luminance. Another luminance analysis system called “Cap-Calcul” in the early 1990s improved on previous developments by introducing a variable focal length lens. It had an improved luminance range also of between 70 and 27,000 cd/m² (Rea and Jeffrey, 1990).

Bellia and Spada note, “Berrutto and Fontoynt (1995) set up a portable system for wide-angle luminance mapping. This system was connected to a computer for automatic setting and for the storage and processing of data. In particular the setting of the sensitivity range (i.e., the adjustment of the quantity of light), was carried out by means of an electronic shutter driven by software acting on exposure times, abandoning the technique of acting on lens aperture. All the problems connected to film were swept away by the advent of digital video and photographic devices based on CCD and CMOS sensors.”

In the last 25 years, video and camera technology has developed significantly and it is now possible to obtain good quality equipment at affordable prices.

Jacobs (2007) notes: “several companies such as Radiant Imaging, Lumetrix, Optronik, Opsira and TechnoTeam produce and sell tools for photometric measurements, while others such as Art-innovation are specialists in the field of instrumentation for spectral analysis.”

Fig. 1 Low dynamic range images with different exposure times. *Source:* Author.

Process

The process for getting luminance charts starts by taking a series of differently exposed images. A calibrated DSLR camera can be used. A number of images from 3 to 8 of the same scene with different exposure are needed. The exposition of a digital camera can be manipulated in different ways: Firstly, the aperture (f-number), secondly the shutter speed (exposure time), and the thirdly by varying the sensitivity of the camera imaging sensor or ISO. Only one should vary; the other two should be fixed. A tripod and a remote camera controller are needed to ensure stability of the camera. The camera and lens should be calibrated by spot luminance measurement using a luminance meter and a known color reference point. The sequence of images obtained will be put together by computer simulation software such as Radiance or photo based applications such as Photosphere. The HDR corrected image will be generated.

$$E = L \frac{\pi d^2}{4 h} \cos^4 \Phi$$

With a typical imaging system irradiance E on a pixel is related to the scene luminance L as described in the above equation (Jacobs, 2007).

Each single pixel on the screen will correspond to a specific luminance value, although this information needs to be extracted from each pixel, as the relationship of luminance to pixel is nonlinear. A false color image can then be generated (Figs. 1–4).

Luminance is measured by using a HDR image technique: Taking photographs (low dynamic range images) using Canon EOS 5D Mark II DSLR camera with Sigma 8-mm fisheye lens, at the same point in time. To obtain stable images, the camera was placed on a tripod at a steady, standing position. The camera was connected to a computer laptop installed with EOS Utility 2 software, which acted as the camera remote controller. By doing so, one would not need to touch the camera directly, thus minimizing the movement of the camera. Changing the shutter speed values, while maintaining the ISO value and aperture as constant, varied the camera exposure setting. The selected shutter speed values were 1/4000, 1/2000, 1/1000, 1/500, 1/400, 1/250, 1/125, 1/100, and 1/25 s, while the ISO value was 100 and the aperture value was 4.0. To calibrate the data, several daylight physical variables, i.e., vertical illuminance and scene luminance, were physically measured; vertical illuminance was measured with a lux meter at various points representing the occupant's point of view. Meanwhile, scene luminance was measured with a luminance meter. Calibration was carried out by marking the area to be calibrated on the HDR image (the same area measured using the luminance meter). The results of the luminance values were then inserted in the calibration column "postprocessing." The photography images that have been taken with a different exposure were then combined to get a HDR image using WebHDR Jaloxa. The HDR images were processed using Hdrscope based on Evalglare software to obtain the daylight variables in terms of average of the total luminance of the scene, as well as the indicators of visual comfort such as Daylight Glare Probability (DGP) and Daylight Glare Index (DGI) glare index.

Applications

The main use of HDR images is for luminance distribution evaluation within the field of view.

High dynamic range imaging techniques are increasingly used in daylight and lighting design as a data acquisition tool for the purpose of acquiring information related to lighting quantity and lighting distribution. Luminance value measurements within the

Fig. 2 Corrected combined HDR image and false color image. *Source:* Author

Fig. 3 LDR to HDR/luminance capture process. Adapted From Jacobs, A., 2007. High dynamic range imaging and its application in building research. *Advances in Building Energy Research* 1 (1), 177–202.

Fig. 4 Image acquisition sequence. Adapted From Jacobs, A., 2007. High dynamic range imaging and its application in building research. *Advances in Building Energy Research* 1 (1), 177–202.

occupant field of view and investigation of visual discomfort are other direct applications. This photographic technique also makes it possible to map sky luminance.

HDR images offer an accurate measure of luminance values within a space; illuminance values can be also detected and false color can be applied to quantitatively analyze the scene.

HRD images can be used for Unified Glare Rating (UGR) measurement and also for glare detection. For the UGR measurement, using photometrically and spatially calibrated images, the exact luminance, direction, and solid angle of each pixel is defined and the UGR glare rating or different glare indices such as DGI and DGP can be derived.

HDR images can replace, in some cases, sophisticated metrological station monitors when these instruments are used for mapping sky luminance. To optimize building performance, data such as percentage of cloud cover and daylight hours are really important considerations for designers. Existing meteorological stations provide this data using costly scanners with limited spatial resolution. HDR

images of the sky can be taken with a 180-degree fisheye lens that provides a better spatial resolution. This data can be then analyzed using different software. Only the number of pixel on the camera limits the quality of the data from this method of measurement.

The affordability and effectiveness of luminance chart data, along with the small amount of error using this technique, have supported the development of different technique applications within the artificial light and daylight research and practice sectors. An example of such work is the measure of complex luminous fluxes across large areas, the enhancement of complex luminance based evaluations for design purposes and some alternative lighting metrics such as mean room surface exitance measurement, climate-based daylight modeling (CBDM), etc., (Cuttle, 2010).

CBDM is the prediction of various radiant or luminous quantities (e.g., irradiance, illuminance, radiance, and luminance) using sun and sky conditions that are derived from standard meteorological datasets. Climate-based modeling delivers predictions of absolute quantities that are dependent both on the locale and the building orientation, in addition to the building's composition and configuration. HDR images are used to create a database of daylight related information usually gathered within a year, that have been found to be as reliable as the ones from standard meteorological stations.

Other fields of application relating to daylight and lighting using video luminance meter include:

- Lighting control for museums
- The control of light pollution
- Energy saving
- Evaluation of visual comfort in indoor and outdoor environments
- Availability of daylight
- Measurements in scale and full scale models
- Photometric measurements for data collection
- Glare

Cuttle (Bellia and Spada, 2014) and others are currently exploring the use of HDR imaging as a new lighting metric because of its direct relationship with what we see that can be measured in lighting terms. This research is currently being carried out in a new area of artificial lighting science known as mean room surface existence (MRSE). This technique also allows for the possibility of light pattern modeling.

Despite a significant number of research papers on the subject of HDRi, it is widely acknowledged that a standardized method for capturing and processing of LDR to HDR and luminance mapping is required (Cai and Chung, 2011).

HDRi images can be evaluated for glare with the software Evalglare. It has three different algorithms, one of which is "task luminance," which can be used to compare and calculate which areas in the task area are a multiple of the average luminance of that area (Rodriguez et al., 2015).

HDR imaging has been used in conjunction with LMK software, to compare the accuracy of glare prediction with Dialux, an industry wide lighting software package. A subjective assessment shows HDRi to be more accurate for the prediction of glare when compared with the subjective evaluation (Jacobs, 2007).

Conclusion

As technology develops, the desire and need for a greater number of professionals applying the various applications of HDRi metric becomes more attainable and desirable. Not least because of the legibility of the technique as an image based application for the lighting professional and wider built environment community, but also because the accuracy of the process will improve and expand as technology develops as is evidenced by its history. As it becomes more commonplace, in time it will inevitably fulfill its potential for a myriad of lighting and daylight applications.

Looking to the future for HDRi the following quote sums up what we can hope for:

"High dynamic range (HDR) images and video contain pixels, which can represent

much greater range of colors and brightness levels than that offered by existing,

standard dynamic range images. Such "better pixels" greatly improve the

overall quality of visual content, making it appear much more realistic and appealing

to the audience. HDR is one of the key technologies of the future imaging

pipeline, which will change the way the digital visual content is represented and

manipulated." (Mantiuk et al., 2016)

Multiple HDR video imaging techniques are already in use in the assessment of light distribution in different scenarios. So it is not unreasonable to expect this type of application where light entering the eye of the viewer in motion can be measured accurately in the near future.

Induction Heating in Sustainable Manufacturing and Material Processing Technologies – A State of the Art Literature Review

Ankan Mishra, Swarup Bag, and Sukhomay Pal, Indian Institute of Technology Guwahati, Guwahati, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The rate at which the modern materials are being developed, the processing techniques also gets updated to deal with the advanced materials or biomaterials. High productivity, ease of processing, optimum utilization of resources, minimum negative impact on environment is the desirable criteria for modern material processing techniques. Heating is the primary requirement of every material processing technology and it is also the cause of emissions, environmental pollution, and contamination. Conventional heating method used in manufacturing processes use fossil fuels, petroleum products etc., which generate a considerable amount of gasses like fluorides, carbon monoxide, carbon dioxide, and other hydrocarbons leads to pollution, greenhouse effect and acts as a barrier in the process of sustainable manufacturing (Popović *et al.*, 2014; Szewczyńska *et al.*, 2015; Jin *et al.*, 2017; Ma *et al.*, 2019). Thus, there is a need for choosing a heat source that is sustainable in nature and able to produce clean technology. Induction heating is a non-contaminated, emission-free sustainable process making it popular among the available sources in recent times. It offers uniform heating, faster rate, consistency, flexibility, and ease of use for intricate shapes and sizes. Latest induction heating system offers the options for accommodating different part geometries, usability on vast material dimensions from very thick steel pipe to small scale material processing like nanotubes and powders at confined space (Lupu *et al.*, 2004; Li *et al.*, 2008; Grande *et al.*, 2012; Rashad *et al.*, 2012). It also offers ease of use no matter the weather conditions but gas (mostly inert gas) shielding should be used if the material has oxidation prone. Various configuration of induction coil is available that sit on the top of a substrate and may not necessary to be wrapped around the workpiece. Induction heating is applied directly on conductive materials, however, non-conductive and nonmagnetic materials can be heated through the use of susceptors which transfers heat to nonconductive parts and assist indirect heating of these materials. In effect, susceptors act as a passive medium to make non-conductive material absorbing heat indirectly and perform like a conductive and magnetic metal (Bayerl *et al.*, 2014). In principle, the process of induction heating is similar for all applications, but there is always a difference in intensity and distribution across all manufacturing processes. In some application, heating rate as well as heat flux intensity requirement is low and in some cases, it is very high. Therefore, based on low or high frequency, the application of induction heating is categorized (Ahmed *et al.*, 2005; Bayerl *et al.*, 2014; Lucía *et al.*, 2014). Also, the coils are always custom built according to the shape and size of the substrate material. Coil geometry is a major challenge in producing the required eddy current at specified area. In most of the applications, the methodology is similar, but, the coil geometry, use of shielding gasses to protect heating zone, use of magnetic shielding to protect nearby area and magnetic flux concentrator to increase the heat flux, specific design of fixture, frequency in use, time duration, exposure area etc., are the factors that differentiate each application of induction heating from another.

Sustainable manufacturing modestly refers to satisfying the need of future generation as well as satisfying the need of present generation by minimum utilization of resources along with least impact on the environment. It indicates the development of manufacturing processes that are energy efficient i.e., consuming lesser energy (may be hydro-power, wind, electrical), use of bio-degradable raw materials, production process with lower maintenance, and minimization of waste products and emissions. According to Badurdeen and Jawahir (2017), there are four steps in sustainable manufacturing that are pre-manufacturing, manufacturing, use, and post-use and it incorporates a 6R policy i.e., Reduce, Redesign, Reuse, Recover, Recycle and Remanufacture. Furthermore, sustainability in the manufacturing process is primarily assessed on the basis of the consumption of natural resources and environmental emissions. Fig. 1 depicts the relation between resource consumption and environmental hazards for different manufacturing systems. It is obvious that both the use of natural resources and the creation of environmental hazards and emissions are substantially reduced from traditional manufacturing to sustainable manufacturing in comparison to the green manufacturing system. In contrast to green manufacturing where only the process is emission and hazard free, sustainable manufacturing encounters the green manufacturing process, satisfying the need of future generation by consuming lesser natural resources and contributing almost zero emissions to nature. Hence, sustainable manufacturing accounts the benefit of green manufacturing apart from minimum resource utilization. Although electromagnetic induction heating is a cleaner technology, the manufacturing processes developed by utilizing this heating method may not always be sustainable in nature. The factors like the minimum waste products by optimum utilization of resources, minimum energy, and water consumption, maximum utilization of renewable energy may not be feasible always to develop a sustainable process. Eastwood and Haapala (2015) indicate that the sustainability performance should contemplate economic, environmental, and social features concurrently and include the elements like manufacturing-associated expenditures, energy and material use, and manpower related medical issues. In general, the conservation of energy, energy efficiency, and energy waste of a process is the key measurement of sustainability. The induction heating is the most energy efficient and fast heating process as compared to other conventional systems. However, the sustainability of industrial process developed by induction system depends on how the heating process has been adopted according to the complexity of the manufacturing systems. Generally, the induction heating system fit to the existing production line with relatively ease and efficient way as compared to other heat source utilization.

Fig. 1 Natural resource consumption and emission from different manufacturing ideologies.

Electromagnetic induction heating, a green technology is used for several material processing technologies like casting, forming, welding, heat treatment, curing and annealing of metallic materials and processing of non-metallic materials (Hong-ming, 2010; Yan *et al.*, 2010; Pappadà *et al.*, 2015; Smusz *et al.*, 2018). Induction heat treatment of shape memory alloy is one of such applications to provide the desired memory effects in alloys like nitinol. Nitinol is the most used alloy in the biomedical application and is used as stents during heart blockage (Haldar and Lagoudas, 2018). Also, in the aid of sustainability of conventional heating processes, the induction heating process is being used to improve the calorific value of lower rank coke and enhance their metallurgical properties too (Valia and Harrison, 1994). Biofuels are now being produced with the help of induction heating methods which is another step towards sustainable manufacturing. Napier grass is regarded as an exceptional non-forage green stock to produce energy as it grows fast and is a low nutritional demand bioresource with high yields of moisture-free matter. Bio-oil production from Napier grass through induction heating has been effective due to its non-emissive nature and fast process time (Lee *et al.*, 2010). Similarly, induction heating is used to convert food processing and industrial sewage into bio-oil separating them from polycyclic aromatic hydrocarbons which are a matter of environmental concern to contribute greenhouse pollutants. However, induction heating pyrolysis is an effective method to treat food and industrial sewage, and to obtain bio oil for future generations (Tsai, *et al.*, 2009a,b). Another sustainable application of induction heating is bio-gas reformation aided by wind energy. This is a process of reforming renewable energy using sustainable heating approach, which might be the best multi-technology approach to date. Fig. 2 describes a setup that transforms a mixture of biogas with some amount of carbon dioxide and inert gas to synthesize gas with the help of wind power and induction heating system via an energy storage medium. This system is fed with a mixture of methane and carbon dioxide which are major components of natural biogas with the addition of inert gas. The mixture is then induction heated through the reactor to provide fast heating that converts the natural biogas to synthesized gas having a higher heat value. With the use of the induction heating process, high and stable conversion rate was achieved as well as the qualitative value of the biogas which is an also renewable gas was enhanced. In effect, very quick response time, low carbon deposition and low inertia make the induction heating process a preferable choice over other methods (Pérez-Camacho *et al.*, 2015). Since thermalization is essential for all manufacturing and material processing techniques, induction heating process finds its use in a broad spectrum of application.

Sustainable manufacturing is also introduced at the forefront of an environmental issue such as cleaning up of existing pollutants and accordingly the material processing techniques has been developed. A novel thermal drying of sewage sludge (heat treatment) with the application of induction heating has been designed (Fig. 3). The sewage sludge is collected after mechanical dewatering with chemical treatment from the plant. Three iron media (as susceptors) i.e., electromagnetic induction net (EMI-N), electromagnetic induction fiber (EMI-F), and electromagnetic induction plate (EMI-P), respectively, are used in this process. EMI-F and EMI-N are mixed with the earlier treated sludge and EMI-P is used as a container to collect the fine layer of sludge in it. The electromagnetic induction heater is used to dry the sewage sludge for treatment. There is the rapid formation of cracks and sewage sludge shrinkage after moisture evaporation. This reflects the process capability of induction heating to clean up the sewage sludge for commercial application (Xue *et al.*, 2018).

In general, the conventional heating process is used in the casting process which is associated with environmental issues. In continuation of the application of induction heating for the development of casting technology of steel is more sustainable to its conventional counterparts. It provides fast heating rates which prevent oxidation with negligible emissions. Also, there is no product contamination as induction heating is a non-contact process (Hong-ming, 2010). Apart from the casting process, the use of induction heating for warm forming of stainless steel has been developed. The setup generates a heat flux of asymmetric pattern in the formable zone which leads to the variable temperature gradient. However, this asymmetric pattern may not always desirable for a sustainable warm forming process. The lack of use of magnetic flux concentrator is the sole reason for the cause. Further

Fig. 2 Schematic setup of biogas enhancement by using wind energy and induction heating. Reproduced from Pérez-Camacho, M.N., Abu-Dahrieh, J., Rooney, D., Sun, K., 2015. Biogas reforming using renewable wind energy and induction heating, *Catalysis Today* 242 (Part A), 129–138.

Fig. 3 Schematic of sewage sludge treatment by application of induction heating method. Reproduced from Xue, Y., *et al.*, 2018. Thermal treatment on sewage sludge by electromagnetic induction heating: Methodology and drying characterization. *Waste Management* 78, 917–928.

modification of setup with the use of latest magnetic flux concentrator would optimize the heating process and would lead to better quality of products (Smusz *et al.*, 2018). Further, induction heating has been used for hardness compensation, stress relieving or addition, and defect rectification (Babakri, 2010a,b; Paquet *et al.*, 2014; Eastwood and Haapala, 2015; Sorrija and Nascimento, 2017; Udhayakumar and Mani, 2017). While induction heating is a commonly used method for heat treatment in manufactured pipes and welded components, this method also gives great flexibility and advantage in welding applications involving other intricate shapes including the flat plate. Welding using induction heating is a great step towards sustainable manufacturing as it produces no smoke and emissions to the environment. Mostly, the induction coils used are circular in nature that is utilized to develop the joining of pipes extensively. The welding method is well set for various materials like high strength low alloy steel, structural reinforcement steel, corrosion resistant stainless steel, dissimilar combination of cemented carbide and alloy steel, but, there is no limitation on the quality and dimension of welding specimen as it all depends on the design of coil that can be manufactured according to the requirement (Wang *et al.*, 1999; Yan *et al.*, 2011; Huang *et al.*, 2013; Ju *et al.*, 2014;

Fig. 4 Schematic for the application of induction heating in welding of non-conductive and conductive materials. Reproduced from Ahmed, T.J., Stavrov, D., Bersee, H.E.N., 2005. Induction welding of thermoplastic composites-an overview. *Composites Part A: Applied Science and Manufacturing* 36 (1), 39–54.

Udhayakumar and Mani, 2017). In principle, the induction heating requires the work part to be conductive. However, non-conductive or non-magnetic materials, non-metals, and composites are processed with the help of metallic susceptors that indirectly transfer the heat. Fabrication of composite panel, welding of the thermoplastic composite, aluminum-nitride-graphene composites, carbon-fiber reinforced thermoplastics are some of the focus areas in which induction heating has found its application towards the development of sustainable manufacturing of composites (Rudolf *et al.*, 2000; Pappadà *et al.*, 2015; Shon, 2017; Shon and Kim, 2017). Zeolites were also synthesized using the induction heating process without any environmental emissions. The mobile heating of accelerating ions takes the working temperature to crystalline temperature early and hence faster zeolite formation takes place in this case. Further extensive research is suggested to find out an optimal window for zeolite synthesis (Slangen *et al.*, 1997).

It is obvious that induction heating is applied in most of the material processing technologies starting from the production of bio-oils, sewage treatment to manufacturing and heat treatment processes. It is preferred where the application of thermal energy in a controlled rate is the primary requirement. This is an indirect boon as induction heating technology is relatively clean and do not contaminate the environment by emissions. However, the material processing technology using the induction heating may not utilize the resources in an optimum way or may not minimize the waste product. Hence, the present article investigates the application of induction heating in different manufacturing processes and how the sustainability of these processing technologies is evaluated. The principal, details methodology, and applications to different manufacturing processes are analyzed in subsequent sections.

Principle of Induction Heating

The basic elements of the induction heating system consist of frequency inverter, transformer, capacitor, induction coil, and the workpiece. The transformer is optional and utilized to adopt the required current and voltage that finally leads to generate the magnetic field. The capacitors may be a part of the inverter that helps to create the desired resonance frequency. When an alternating current pass through the induction coil, it creates a magnetic field around it. As the magnetic field passes through the workpiece, it generates eddy current in the workpiece material. The resistance of the metal fights against the flow of the eddy current which leads to the heating of the workpiece by the principle of Joule heating. If the work part is magnetic, then hysteresis loss provides additional heating until the Curie temperature of the working material after which only the Joule's heating is left with. Conductive and magnetic materials are directly heated through induction coil but heating of non-conductive and non-magnetic materials require special arrangements such as susceptors. Fig. 4 shows that secondary heat carrying material is designed to transfer the heat flux generated by the eddy current. The important process parameters are found to be coil geometry, magnetic flux concentrators (impeders), coupling distance, frequency, and inductor current. Also, some of the major effects associated with electromagnetic induction are skin effect, proximity effect, ring effect and edge effect (Ahmed *et al.*, 2005; Bayerl *et al.*, 2014).

Eddy Current Heating and Hysteresis Losses

From Faraday's Law, due to the varying alternating magnetic field of the coil induced currents called eddy current (also Foucault current) that flow against the electrical resistivity of the metal, contributes to heating of the elements. Eddy current flows through conducting material in closed circular loops, and in a plane that is perpendicular to the magnetic field. The measure of the eddy current in a particular loop is directly proportional to the strength of the magnetic field, the loop area, the rate of change of

Fig. 5 Summary of EMI effect: (a) Skin effect (b) proximity effect (c) ring effect (d) edge effect. Reproduced from Bayerl, T., *et al.*, 2014. The heating of polymer composites by electromagnetic induction – A review. *Composites Part A: Applied Science and Manufacturing* 57 (2014) 27–40. Rapoport, E., Pleshivtseva, Y., 2007. *Optimal Control of Induction Heating Processes*. Boca Raton: CRC Press.

magnetic flux, and inversely proportional to the resistivity of the material. Lenz's law states that the magnetic field created by the eddy currents repels the source magnetic field that created it. Under the quasi-static condition, power lost (P) due to eddy current is calculated as

$$P = \frac{\pi^2 B_p^2 d^2 f^2}{6k\rho D} \quad (1)$$

where ρ is the resistivity of the material (ohm m), D is the density of the material (kg/m^3), f is the frequency (Hz or kHz), B_p is the peak magnetic field (T), k is the constant equal to 1 for a thin sheet and 2 for a thin wire, and d is the thickness of the sheet or diameter of the wire (m).

Hysteresis loss can be defined by the energy loss due to the reversal of magnetic dipoles when magnetic material come in the influence of alternating magnetic field. This energy loss in the form of heat is used in induction heating till Curie temperature is reached after which the material loses its magnetic property. It is proportional to the frequency of the alternating current that is used to generate the alternating magnetic field (Zinn and Semiatin, 1988; Cheremisinoff, 1996; Bayerl *et al.*, 2014). Under the quasi-static condition, the power loss due to electromagnetic hysteresis is estimated as

$$W_h = K_h f B_m^n \quad (2)$$

where K_h is the material hysteresis constant, B_m is the maximum flux density (Wb/m^2), n is the Steinmetz exponent (varies from 1.5 to 2.5 and it is 1.6 for iron). The total power loss due to eddy current heating and hysteresis loss is equivalent to net heat generated during the induction heating process. Further, due to an alternating magnetic and electric field, different types of consequence effects are observed which are explained in subsequent sections.

Effects Due to Electromagnetic Induction

Skin effect

When the frequency of the alternating current creating magnetic field is very high, the eddy current produced does not penetrate deep into the material and tend to flow on the surface. The amount of current flow reduces from the surface to the interior of the material irrespective of the dimension and nature of magnetic material. It is known as the skin effect and is depicted schematically in Fig. 5(a). This skin effect renders the quasi-static condition of eddy current loss and approximately 86% of power is concentrated on the surface or skin depth. The skin depth (δ) for a good conductor can be calculated as

$$\delta = \frac{1}{\sqrt{\pi f \mu \sigma}} \quad (3)$$

where σ is the electrical conductivity of the material (S/m), and μ is the magnetic permeability of the material (H/m). The depth at which the eddy current is 37% or $1/e$ in comparison with the surface value is called the skin depth and at this depth, the power density is $1/e^2$ or 14% of the surface power density. The current diminishes exponentially as

$$I_x = I_0 e^{-\frac{x}{\delta}} \quad (4)$$

where x is the depth from the surface (m), I_x is the current at depth x with respect to the surface (A), and I_0 is the current at the surface (A). The frequency is an important process parameter for controlling of skin depth and thus temperature rise in the edges. In high-frequency induction welding (HFIW), the skin effect results in the current flowing only on the material surface and edges to heat it to the melting temperature (Bayerl *et al.*, 2014).

Proximity effect

Eddy currents cause secondary magnetic fields around the path they are flowing. When two nearby work parts have induced eddy current and subsequent magnetic field, they tend to get attracted towards it, which is mainly beneficial in case of induction welding. This effect is known as the proximity effect. This further helps to increase the current density at the edges. Fig. 5(b) schematically describes the proximity effect.

Ring effect

This effect is mainly observed when circular coils are used. The magnetic field lines get concentrated in a circular path and leads to the heating of the coils. However, it is not a desirable phenomenon with any kind of applications and can be reduced by the use of magnetic flux concentrator or impeder at the target zone (Fig. 5(c)).

Edge effect

When there is a difference in magnetic permeability of the work parts that results in a change of electrical path and field lines, it is known as the edge effect. This results in an undesired heating pattern in the work part. Fig. 5(d) depicts the edge effect in induction heating.

Importance of Impeder

The objective of using an impeder is to focus the magnetic flux to the desired location. It is achieved by increasing impedance of the current path at the heating location, hence, concentrating more current at the heating zone. The efficiency of the use of impeder depends on impeder material, design, and placement. The impeder is desired to have maximum saturation flux density and amplitude permeability with negligible electromagnetic losses. The position of impeder around the heating zone is also extremely important. An impeder is most advantageous if used close to the desired heating zone (Ahmed *et al.*, 2005; Bayerl *et al.*, 2014). The analysis of the effect of impeder was also studied and few results like microstructure and the effect of process parameters have been reported.

Continuous efforts are going on to improve the fatigue life of induction welded micro-alloyed steel tubes. However, the process is interacted with several parameters like strip width, V-length, impeder diameter, heat input, and V-angle that affect the fatigue life. Optimal parameters lead to better quality of weld characteristics. When the welded tubes are heat treated at sub-critical temperature of 650°C or 700°C, there is significant improvement of fatigue life (Udhayakumar and Mani, 2017). During the welding of metallic tubes, the magnetic flux around the weld zone is concentrated by the use of impeder. It was observed that upon changing the impeder position with respect to the welding zone affects the temperature distribution. It is due to change in current concentration and focusing of the magnetic field around the weld zone and subsequent generation of heat. When the impeder is exactly positioned over the weld zone, better quality of the weld is obtained (Spahiu, 2007). A new magneto-dielectric (MD) material is proposed i.e., Fluxtrol for the impeder and a two-step heating process for the improvement in high-frequency welding is suggested. The positioning of impeder decides the passage of magnetic lines of force through the work part under or above which the impeder presents. The heat generation is concentrated over that region as shown in Fig. 6. Further, by use of Fluxtrol, there is no increase in carbon implying the good quality of weld with better microstructures as shown in Fig. 7 (Milicevic and Radakovic, 2006).

Coil Design

Induction heating coil design is an integral and basic need while thinking of the application of induction heating in any material processing and manufacturing process. The coils used in induction heating are generally made up of pure, oxygen-free copper those are brazed with cooling tubes to lower their electrical resistance. Eddy current generation by the varying magnetic field produced by work coils and subsequent heat generation is the base of induction heating mechanism. So, it has to be designed in such a way that the desired work area gets the required amount of heat. Depending upon that single turn, multi-turn, and pancake type, the design of the coils exists. Fig. 8 illustrates some commonly used induction heating coils. A single turn circular coil produces a magnetic field that is focused around its coil diameter and is mostly used for circular workpieces like pipe and rods to perform welding and heat treatment processes. In comparison with single turn coil, multi-turn coils provide more symmetrical heating zone. Pancake coils are used where flat surface heating is required and it provides good localization of heating. Further, hairpin coils are used where miniature work parts with localized heating are needed. On the other hand, split coils are used for

Induction welding of thermoplastic composites-an overview. *Composites Part A: Applied Science and Manufacturing* 36 (1), 39–54.

customized heating of work parts. It is thus obvious that depending upon the application and substrate geometry, the coils can be designed accordingly. The coil diameter, no of turns, the air gap between the coils also affect the generation of required magnetic flux and hence heat generation (Ahmed *et al.*, 2005). The magnetic flux (ϕ_β) generated by an induction coil is estimated by approximation of Ampere's law as

$$\phi_\beta = (\mu_0 I_C n) (\pi r_0^2) \quad (5)$$

where, r_0 is the mean radius of the coil turns, I_C is the coil current (A), μ_0 is the permeability constant $= 4\pi \times 10^{-7}$ (Wb/A m), and n is no of turns in the coil. Eq. (5) indicates the flux generated from an induction coil without the use of any impeder. The variation of the magnetic flux generated or the heat flux generated with respect to coil current, no of turns of coil, and the coil radius can be derived from this equation.

Current Research and Applications of Induction Heating

Heat source at different intensity has been the essential component of material processing technologies since the beginning of the manufacturing industry i.e., from casting to heat treatment. In recent times, sustainable manufacturing and processing is a prime concern to the industry and hence the utilization of induction heating is an opportunity to develop a sustainable process. Induction heating is a non-contact process with least impact on the environment and hence, is preferred over the rest of the available sources. The heating through induction heating is mainly through eddy current by Joule's heating and magnetic hysteresis loss till the Curie temperature. Since polymers are non-conductive, it is heated through a susceptor and the heating is affected by its properties like Curie temperature, density, heat capacity, magnetic and electrical property. Broadly, induction heating applications are categorized in two groups depending upon the frequency in used i.e., high and low frequency. Lower frequency applications include casting, forming, waster treatments etc., where entire substrate heating is required and higher frequency is used where a localized heating is needed like welding, localized stress relieving etc. This difference is due to the effect of skin depth achieved during the process (depicted by Eq. (3)). Lower frequency leads to higher skin depth and consequently promotes in-depth penetration. The induction welding operation can be carried out in two modes of i.e., thermal mode and electric power mode. When the skin depth is larger than thermal depth, the welding is performed under electric power mode and the opposite is termed as a thermal mode. Lowest welding power requirement, narrowest HAZ and least sensitivity to process parameters are observed in a thermal mode in comparison with electric power mode (Scott, 1999).

Thus, the induction heating process has taken a shift to industries in recent times due to increasing demand of sustainable manufacturing process and government regulations. A wide variety of applications of induction heating for various material processing operations like casting, welding, production of bio-oils, heat treatment operations, manufacturing of polymers and composites has been explored in this section. The induction heating application has intruded into so many areas that it now becomes an emerging sustainable heat source and the researchers are exploring the benefits out of it.

Welding

Induction welding is advantageous over arc welding processes as it is a non-contact and environment-friendly process. The heat is produced within the part itself and the efficiency of the heat transfer rate is relatively high (~60%). High quality and stress-free welds are produced without the use of filler material. There is no need for surface treatment before the start of welding process. Since there is internal heat generation inside the work part that distributes over the volume, there is not much thermal stress developed within the processed zone. Still, there is some issue with welding using induction heating. There may be decarburizing in the weld zone of the part produced and cost involved in developing and optimizing the work coil, and the design of fixture (Wright, 1999; Rudnev *et al.*, 2003; Frogner *et al.*, 2011; Lucía *et al.*, 2014; He *et al.*, 2017; Troughton, 2017). Till date the focus has been preoccupied mostly with welding of seamless steel line pipes but, the welding of high strength low alloy steel, structural reinforcement steel, stainless steel, dissimilar welding of cemented carbide, alloy steel has also been performed. There is a no restriction on size and shape of welding as it all depends on the custom coil geometry according to the dimension of work material (Wang *et al.*, 1999; Huang *et al.*, 2013; Ju *et al.*, 2014; Udhayakumar and Mani, 2017).

In comparison with the arc welding process, the induction welded specimens were found to have better metallurgical properties. In welding of reinforcement steel, there is an increase in hardness in welded areas is approximately 30% by induction heating as compared to arc welding. Even, the hardness values increases from 80 to 115 HBN if welding duration is increased from 2 to 5 min (Sari, 2016). Further, induction welding of dual phase steel shows that heating rates to be significantly different before and after the Curie temperature. However, a complete coalescence of the welding surface was achieved with minor hardening. This concludes that high-frequency welding has potential for joining of coils in steel processing lines (Baumer and Adonyi, 2009). Stainless steel wires were also welded using a frequency of 2 MHz with argon shielding gas. Fig. 9 illustrates the schematic setup for induction welding of steel wire. Inside a quartz tube, the welding operation has been carried out with the inert gas atmosphere. Infrared pyrometer was used to record the temperature. Steel wire was welded after aligning inside the induction coil. Tensile strengths of the joints were found to be superior at higher welding temperature (1050°C) in comparison with lower temperature (1030°C). Small holding time or lower heating temperature resulted in lower ferrite formation and vice versa. Higher temperature or longer holding time resulted in a reduction in the cooling rate and hence higher ferrite count was observed (Huang *et al.*, 2013). Apart from welding of steels, the welding of dissimilar

Fig. 9 Schematic of induction welding setup for steel wire. Reproduced from Huang, C.-Y., *et al.*, 2013. Rapid welding of stainless steel wires using ultra-high frequency induction heating. *Journal of the Chinese Institute of Engineers* 36 (6), 806–809.

cemented carbide and alloy steel using brazing filler metal (Cu-Zn-Ni-Mn alloy) has also been reported. It was found that the heating and cooling rates affect the residual stress largely. The residual stress influenced by cooling rate in cemented carbide was more sensitive than steel (Ju *et al.*, 2014). With decrease in heating rate, the residual stress reduces in material and a big drop is observed at higher range of heating rate than lower range. In induction welding of iron-based powder-metal bearing, the joining surface area increases with processing time whereas the hardness decreases with processing time. The grain growth occurs at the welded zone and a coarse grain structure imparts low hardness value. With decrease in processing time, the hardness values of the bearings increase from 50 BHN to 62 BHN. The bending strength and tensile strength values are also higher than the base material (Çavdar and Gülşahin, 2014; Çavdar and Kusoglu, 2014; Sari, 2016). During induction welding of pipes, hydrogen induced cracking (HIC) is sometimes developed due to the influence of residual stress. Cold forming of the steel rolls before the welding process is the main reason for the developed residual stress which has a negative influence on the resistance of pipes. It was inferred that both longitudinal and circumferential stresses have no negative influence on the welding of pipes through induction heating. Apparently, with the help of the residual stress HIC damage can be minimized (Gungor *et al.*, 2010).

The analysis of the process parameters in finding out an optimal window for defect-free welding is also significant in reference to the process repeatability and precision welding. The application of induction heating is a boon in the field of welding as most of the conventional heat sources contribute to environmental hazard as well as pollution. Secondly, this is a non-contact process hence chances of weld contamination by secondary elements is less. Thirdly, the process produces defect-free, stress and distortion free welds with narrow heat affected zone. Still, there is a need to design appropriate coil according to requirement and its positioning. Proper design of fixture, selection of inert gas shielding, use of magnetic flux concentrator for optimizing the heating zone may result in improved product quality, lesser use of natural resources and reduction in environmental contamination.

Heat Treatment

The application of induction heating in heat treatment processes is an important tool as it can reach out in mobile locations by custom coil. Heat treatment by induction heating is being carried out by industries for seeking out sustainable manufacturing processes (Eastwood and Haapala, 2015). The heat treatment processes are generally used for stress and hardness compensation those are either generated due to conventional heating process or by use of induction heating process. The heat treatment of micro-alloyed steel pipe has been conducted to relieve the residual stresses developed during the welding. Fig. 10 illustrates the schematic of the induction heat treatment setup. The setup constitutes of induction coil, water cooling system to keep the coil at room temperature, argon gas shielding to prevent oxidation and the required control unit (Çöl and Yilmaz, 2006). Often, in a welded structure, a predetermined amount of tensile surface residual stress is introduced for enhancement of fatigue life. In high strength low alloy steel, after 50,000 cycles which correspond to its half-life, compressive residual stress was found on the specimen surface (Paquet *et al.*, 2014). In post weld heat treatment of micro-alloyed steel tubes, optimal selection of process parameters like V-angle, V-length, strip width, impeder diameter, and heat input leads to better mechanical properties and also enhance the fatigue life (Udhayakumar and Mani, 2017). However, the analysis shows that the weld line acts as a stress enhancer and hence reduces the fatigue resistance (Sorrija and Nascimento, 2017).

Studies on the failure of the induction welded pipes in the flattening test reflect that there are two major defects i.e., the cold defect and the penetrator defect, where the former is due to lack of power and the latter is due to excessive power. Oxidation of the weld zone is one of the factors for flattening failure of the welded pipes. Post weld heat treatment to normalize the welded pipe at austenitic temperature is suggested for the improvement (Babakri, 2010a,b). It reduces the residual stress and brings uniformity in hardness

Fig. 10 Schematic of induction heating treatment setup. Reproduced from Göl, M., Yilmaz, M., 2006. The determination of heat treatment parameters of X52 micro alloyed steel after high-frequency induction welding. *Materials and Design* 27 (6), 507–512.

distribution at the welded structure. Weld joints of steel are found to be associated with inclusions of manganese and silicon oxides as well as aluminum and calcium-rich oxides. The heat treatment was unable to affect any inclusion. However, grain structure was found to be coarser than base material after heat treatment (Yan *et al.*, 2010a,b, 2011). Extensive research has been carried out for process improvement and defect rectification during heat treatment by induction heating system. There are issues associated with an uneven distribution of hardness and residual stresses in a welded structure. Generally, heat treatment is carried out to neutralize these effects. In the case of micro-alloyed HSLA steel, it has been found that due to their homogeneous microstructure the mechanical properties of the base, HAZ and weld zones are similar. It is concluded that Nb-micro-alloying restricts ferritic grain growth and provides strength to the ferrite by precipitate hardening during the heat treatment process (Tazedakis *et al.*, 2010).

It is obvious that most of the welded structure is associated with uneven distribution of residual stress that essentially reduces the fatigue life of the specimen. The effectiveness of heat treatment process releases the residual stress at a certain extent and may bring uniformity in hardness distribution in the weld zone. However, the speed of heat treatment process affects the weld quality. If the heat treatment speed is too low, then coarse grains are formed. At high heat treatment speeds, there are chances of incomplete process and decarburization of the weld zone may lead to the presence of residual stresses at high pace. In general, the induction heating process finds its application in the heat treatment process due to its localized application with low intensity, and fast heating process. The use of induction heating on the heat treatment process for different types of materials is ever increasing owing to minimum impact on the environment and to produce a cleaner and sustainable technology. However, the optimal selection of parameters like heat treatment speed, frequency, and coil design has a desirable impact on the effective and sustainable process.

Processing of Non-Conductive Materials

Induction heating also plays an important role in the development of a sustainable manufacturing process for non-conductive materials like thermoplastics, fiber-reinforced composites etc. Heating of non-conductive and non-magnetic materials require special attention as susceptors or secondary heat carrying material that has to be designed to transfer the heat flux generated by eddy current (Bayerl *et al.*, 2014). In the recent scenario, composites are being used due to their light weight and good metallurgical and mechanical properties and cost-effectiveness in comparison to their metallic counterparts. Electromagnetic heating of thermoplastics readily produces reliable seals on the substrate material. The process adapts for deformation and distortion in the parts as voids are filled by the material flow. Since the surfaces are resin-starved they are filled without any effort. Hence, induction welding is precise and distortion free and its rejection rate is very low (Sanders, 1987). Carbon-fiber reinforced thermoplastics were fabricated using the induction heating process. The important process parameters that affect the quality of the product are the distance between induction coil and laminate, electromagnetic frequency, coil geometry, laminate lay-up, and generator power. Heat is only generated when closed fiber loops exist through which current can flow. Eddy current flowing through the carbon fiber laminate results in Joule's heating (Rudolf *et al.*, 2000). Thermoplastic matrix composite and polyphenylene sulfide (PPS) reinforced with carbon fibers were used to fabricate a composite stiffened panel by the application of induction heating. The setup consists (Fig. 11) of a single turn induction coil, compacting cylinder and cooling nozzle. The induction coil is used to heat and melt the composite and then compacting cylinder is rolled along with the cooling nozzle to solidify the sintered matrix composite. Infrared pyrometer was used to record the working temperature of the process (Pappadà *et al.*, 2015).

Fig. 11 (a) Schematic of the induction welding setup; (b) Induction welding setup. Reproduced from Pappadà, S., *et al.*, 2015. Fabrication of a thermoplastic matrix composite stiffened panel by induction welding. *Aerospace Science and Technology* 43, 314–320.

Not only in the fabrication of composites, the curing and density modification of composites through induction heating have also been achieved. From mechanically activated powders (i.e., a mixture of Ti and Al_4C_3), nano-powders of Al-TiC were produced by induction assisted high energy ball-milling. The relative density of the composites was found to be 99.5%. It was observed that the fracture toughness of TiC gets enhanced by the addition of Al (Shon, 2017; Shon and Kim, 2017). The induction welding of thermoplastic composite (TPC) and hybrid material (metal to composite) has been reported. The process parameters that were found to affect the welding characteristics are coil current, frequency, and electrical conductivity of the material (Wan *et al.*, 2014). The high-frequency induction heating was used for sintering of nanostructured CoTi-3ZrO_2 composites. The sintering was done under 80 MPa pressure for the 60 s. Up to 98% density achieved by the use of this process and the process was very fast and effective in comparison to conventional processes. Its hardness value was improved due to grain refinement. Fracture toughness can be improved with the addition of Co-Ti in the composite (Shon, 2016). Nanostructured aluminum nitride-graphene composites were manufactured by high-speed ball milling process and then induction sintered to enhance its mechanical properties. Nearly full density composites were achieved within 120 s of induction sintering of the composites. It was found that the addition of graphene improves the hardness and fracture toughness due to grain refinement (Shon, 2017; Shon and Kim, 2017). In an induction welding process, carbon fiber reinforced polyphenylene sulfide laminates were fabricated. It was observed that due to skin effect, the heat energy distribution mostly concentrated at the surface and later travelled through the plate in the thickness direction. This could lead to deconsolidation and thermal damages. When the carbon-fiber reinforced laminates were induction heated, the laminate thickness was found to be smaller than the penetration depth, (Hümbert, 2014).

The induction heating method has been used for various kind of material processing of non-conductive and non-magnetic materials by the virtue of susceptors. Thus, susceptor design and fabrication is a challenge in this case. Different kind of products starting from composite panels, thermoplastics etc., are manufactured using this process. Still, further exploration of the optimal use of this process will lead us to a sustainable technology for non-conductive material.

Other Applications of Induction Heating

Induction heating finds its application for the development of many trivial material processing technologies like pyrolysis of rice straw, coconut shell, and sugarcane bagasse, synthesis of thermo-responsive fluids, extraction of pectic etc., due to its high heating

rate and non-contamination features. Also, higher yielding and controlled heating help in optimizing the manufacturing process (Schmidt, 2005; Tsai *et al.*, 2006; Idakiev *et al.*, 2015; Zouambia *et al.*, 2017).

Manufacturing of Silicon-Carbide nanowires of range 8–20 nm was carried out by high-frequency induction heating of SiO and activated carbon fibers without the use of any catalyst. Validated morphologies display the quality of nanowires at par with conventionally manufactured nanowires (Zhou *et al.*, 2006). Similarly, single-walled carbon nanotubes ranging from 0.8 to 1 nm and lengths up to 10 μm were synthesized by application of high-frequency induction heating. The fast heating rate through induction helps in preventing the formation of the additional graphitic layer (Li *et al.*, 2008). Further, Fe-Cr nanocrystalline alloy wires are induction heated. The mean temperature of a capillary bath increases on the application of induction heating due to losses incurred by eddy current and hysteresis effect. It is evident that Joule's heating due to eddy current is dominant since at Curie temperature material losses its magnetic property and hysteresis loss ceases out (Gómez-Polo *et al.*, 2012).

Hascoët *et al.* (2018) presented the consumable wire deposition using induction heating to develop additive manufacturing system. This approach by inductive heating controls the temperature gradient between the tip of the wire and the deposited layer. It increases the effective utilization of heat energy as well as the control of metal transfer in a wire-based additive manufacturing technology. Similarly, induction heating has been used for depositing metallic materials with high melting point onto their substrate by a drop-on-demand deposition system at low thermal input. The Inconel 625 metallic wire was melted at 1623 K and deposited on the substrate of same metal successfully. It has been found that the disposition temperature is directly proportional to the current frequency and density (Sun *et al.*, 2019). Catalytic chemical vapor deposition method was assisted by induction heating process in lieu of heating furnace to produce carbon nanostructures. The comparison on the basis of the rate of production of nanofibers with use of conventional furnace and induction assisted furnace was reported. The energy consumption with the help of induction heating was found to be 2–3 times lower than generally used the furnace and with better morphology (Lupu *et al.*, 2004).

The comprehensive literature survey indicates that induction heating has reached almost all kind of manufacturing and material processing techniques starting from high melting point casting to low-temperature sewage waste treatment. It is evident that induction heating has substantial advantages being sustainable in nature to produce a clean technology and act as a flexible heating technique to suit a variety of material processing technologies. Over the days, its application is increasing tremendously. However, there are challenges to use this clean heating technique for the development of manufacturing processes.

Challenges With Induction Heating

With flexibility in the system, ease of handling, wide range of applications of induction heating, and its sustainability, there are some minor points of concern in actual industrial practice. The requirement for custom-built coil for an individual application, the high cost of equipment, the design of susceptor for nonconductive specimen, necessity of skilled labors and material compatibility are some of the issues that need immediate attention. Still the process being sustainable in nature, its demand is ever increasing and widening its application range over day by day. Since it is a non-contact process and the heating pattern is based on the generation of magnetic field and eddy current distribution on the work part, the design of induction coil is a challenge to enhance the thermal efficiency. In certain applications, the localized heating is important whereas throughout heating over a large volume are significant in some cases (Bayerl *et al.*, 2014). Although induction is a cost-effective method, a number of limitations are associated with conventional induction heating technology. Provision for water cooling system of the coils brings additional cost and complexity of the system. The magnetic field may create health hazards for open coil system without any shielding option. Uniform heating over a large area is difficult to obtain with the conventional system (Frogner *et al.*, 2011). The analysis was carried out using induction heating of an injection mold using the single-layered, double layered and triple layered coil. The single layer coil produces asymmetric magnetic field and hence the heating pattern is non-uniform, whereas multi-layered is found to be in better correlation for practical use with symmetric field and symmetric temperature profile in comparison to the single and triple layered induction coil (Huang and Huang, 2010). The coil design is an important aspect for a crystal growth system like high melting oxide Czochralski system. The alignment of the crucible and the coil is utmost important and dependent on their dimension, placement, and orientation to each other. The proper choices of coil type and design are significant for large and moderate growth rate system to develop advanced technology (Tavakoli *et al.*, 2009). Further, in induction heating, non-uniformity in temperature distribution is found due to coil movement which has electrical, magnetic as well as thermal linkage to the work part. The identification of hard (high-temperature gradient) and soft spot (low-temperature gradient) is important in this case. There is a large temperature gradient in the gear ring when the coil traverse speed is slow. At optimum condition, the temperature non-uniformity should be reduced to get precise results (Wen and Han, 2017).

At the initial phase, there were material limitations as only conductive and magnetic material was able to meet induction heated. Now, susceptors help in induction heating of work parts which are non-conductive and non-magnetic. It requires to customize the coil design and susceptors to be manufactured for the development of the process (Bayerl *et al.*, 2014). When there is a requirement of lower heating rate, low Curie-point magnetic materials are alloyed in the work part as the magnetization decreases with an increasing percentage of rare earth metals (Samarium, Gadolinium, Dysprosium, Yttrium) and Al with Curie point in the range of 100–300°C (Todaka *et al.*, 2008). In comparison to traditional oven curing of adhesive, induction heating of adhesives with iron particles as susceptor creates a faster process. But, there was a maximum drop of 15% shear strength using internal susceptor curing whereas it was 6% in external susceptor curing (Severijns *et al.*, 2017). Therefore, the computational model of the induction process is the most convenient way to define the thermal field and magnetic field. However, the cost of

Fig. 12 Schematic of the cooling system by lubricant oil in induction heating process. Reproduced from Kucukkomurler, A., Selver, R., 2012. A preliminary experimental assessment of the utility of magnetic oil for incrementally improving the energy efficiency of an induction heating system. *Journal of Thermal Science and Engineering Applications* 4 (3), p. 035001.

computational time and integration of the subsystems is the major challenge. In most of the cases, the computational design of an induction coil for the required application helps to fabricate the coil (Sun *et al.*, 2013; Nian *et al.*, 2014; Khodamoradi *et al.*, 2015; Lee *et al.*, 2016; Drobenko *et al.*, 2017).

The optimization of heating time, temperature profile, and localized heating of sprockets have been performed using both circular coil and profile coil in induction heating process. Profile coil accomplished higher heating rate and accurate localized heating with lower heating time due to the localization of magnetic flux and corresponding heat generation at that location. Hence, custom made coil is evident to have better efficiency than commercially available general purpose coil (Han *et al.*, 2016). In induction heating process, reduction of thermal losses due to radiation and convection is an important concern as the effective heat transfer is till now 60% and there is a scope of achieving higher heat transfer efficiency. This can be achieved by using proper shielding and design of enclosures so that the heat loss is trapped and utilized (Park and Dang, 2013). The cost of insulation is not high but the design and implementation of it take a major toll to the engineers. It infers that the energy production may be costly, but proper utilization and conservation of produced energy is an important aspect of sustainable manufacturing process.

With several other limitations and challenges for the induction heating system, the sustainability of the process is aided by improving the process efficiency. In most of the cases, the thermal efficiency of induction heating is around 60%. In general, water is used for the cooling of the induction coil. An attempt has been made to use magnetic oil for the cooling purpose in the electro-magnetic heating application as shown in schematically by Fig. 12. The oil pump is used to pump the magnetic oil into the coil and being circulated throughout the process. The objective was to develop a low-cost method to enhance the energy efficiency. The attempt, however, reflects no substantial improvement in the efficiency of the system (Kucukkomurler and Selver, 2012). One of the limitations of induction heating is to produce a uniform temperature of the thin workpiece which is even difficult to achieve using other methods. Use of multiple induction coils has the potential for spatial control of heat generation and permits uniform temperature distribution (Frognier *et al.*, 2011). The zone control induction heating (ZCIH) maintains the same current phase angle at a selective combination of frequencies to prevent interaction. In traveling wave induction heating (TWIH), the combination of frequency and phase shift may produce very high efficiency and uniform heating. The efficiency of utmost 93% can be achieved by using anti-parallel or series connection of inductors with uniform temperature distribution. It is thus obvious that research is going on for improving the effectiveness of the induction heating process by improved coil design, use of multiple coils, proper design of magnetic flux concentrator, improving the efficiency of the heating system, and integrated system design. All these factors are related to the sustainability issue of the process which is in the preliminary stage and needs to investigate from various aspects.

Conclusion and Future Scope

The literature review projects that heat source are essential for a manufacturing unit, but is usually associated with environmental pollution and health hazard due to emissions as a byproduct. Finding a sustainable heat source is a feasible solution to suppress harmful byproducts. The application of industrial heating for different manufacturing processes like welding, heat treatment, brazing, hardening, bonding, sintering, sealing, soldering, drying, curing, degassing, etc., are obvious from literature. Many of these processes are developed using fossil fuel and some of the operations are performed using induction heating. A comprehensive study on the application of induction heating in sustainable material processing and manufacturing technologies has been carried out and the significant features are highlighted. Apart from energy savings, the elite advantages of induction heating are the

reduction of total heating time, positioning to the desired location, and substantial reduction in decarburization, scaling, and unwanted structural changes. Induction heating is also an environmentally friendly process with almost zero emission to the environment. The non-contact process of heating works with the help of eddy current and magnetic hysteresis losses in the work part. Hence, induction heating is being adapted widely ranging from synthesis of chemicals, sewage treatment, production of bio-oils and manufacturing of nanotubes to conventional manufacturing processes like welding, heat treatment etc. The shortcomings of conventional heating methods like slow heating rate, production of emissions, and contamination to parent material are successfully addressed by the induction heating method. The flexibility in coil design and accordingly the controlling of the heating rate makes it possible to apply locally to perform hardening, grain refinement, complete melting like casting and even in wire additive manufacturing process. Frequency selection is an important aspect to alleviate the skin effect. Lower frequency tends to penetrate deep into the material and higher frequency eddy current tend to stay on the surface. In general, the application of induction heating is ever increasing due to the least environmental impact and sustainability aspect as well as a faster process with well-controlled heat affected zone. With proper design of coil and fixture, induction can be applied in a variety of fields where the conventional heating process has limitations. The geometric configuration of multiple coil arrangements and the amplitude and phase shift of applied current may bring a uniform heating pattern which can satisfy a particular need of manufacturing process. Furthermore, magnetic field shaping and obtaining of a temperature profile of desired pattern using shielding and flux concentrator has been given special attention. However, reducing the size of the setup as well as a reduction in radiation and convective losses is a challenging issue. A continuous effort to improve the system performance is going on. Still, there is a huge scope of applying the induction heating in trivial manufacturing and material processing sectors.

Introduction

The world's primary source of energy is fossil fuel, which is nonrenewable in nature and rapidly diminishing. Therefore, researchers are exploring renewable energy sources. Wood and its by-products, which have been used as fuel sources by humans for thousands of years, are receiving more attention in the research domain because they are good, renewable energy sources. In addition, caloric values of biomass such as agriculture and forest residues are being investigated throughout the world.

MacFarlane [1] investigated the urban wood and wood waste of 13 counties in Michigan for energy production. The results suggested that urban trees and wood waste offer a modest amount of biomass that could contribute significantly more to regional and national bio-economies than previously. Caloric values of pine residues that originated from cuts and forestry tasks were studied and measured using a static bomb calorimeter in an oxygen atmosphere [2]. In addition, the effects of the grinder configuration, wood-cutting bit type, and the wood-particle filtering screen size on bulk density and fuel consumption when processing forest harvest residues for energy purposes have been analyzed [3]. The results showed that the fuel consumption was only affected by filter screen size when processing the size class comprising branches and tops.

Sheng and Azevedo [4] proposed a new correlation between the higher heating value and dry ash content of biomass in weight percent using data available from the literature. Wood and Rowley [5] studied the feasibility of a number of biomass-fueled community housing project systems when operated in the context of community housing/mixed use. Six systems comprising differing technologies have been analyzed with the assumption that the systems operate within an energy services company (ESCO) supply scenario. The results have indicated that within specific realistic ESCO operating scenarios, the combined heat and power (CHP) of biomass can demonstrate positive net present values without the need for capital subsidies.

Fifty-two facilities in British Columbia, Canada, were surveyed to gather statistics regarding the rates of fiber use for energy, thermal and electrical energy capacity, and net production [6]. In that research, it was estimated that from 2000 to 2011, an average of 9.4 metric tons (Mt) of wood fiber (oven-dried), or approximately one-third of the total harvested biomass, were used annually to produce energy. Based on the results, it was concluded that wood-based bio-energy supplied approximately 10% of British Columbia's energy demands in 2011. Everard *et al.* [7] studied the accuracy of visible and near-infrared spectroscopy in conjunction with chemometrics to predict gross caloric values of some bio-energy crops. Kumar *et al.* [8] analyzed the fuel wood characteristics of 26 trees, including shrub species, from the dry deciduous forest in the Aravally region of Rajasthan, India. In this work, the fuel wood value index was determined based on the properties of caloric value, wood density, and ash.

Munalula and Meincken [9] investigated six types of fuel woods commonly used in the western cape of South Africa with regard to their caloric values and environmental impacts when burned. Properties such as density, ash content, and elemental composition were determined and related to the caloric value. It was demonstrated that the wood with the highest caloric value was not necessarily the best option as fuel wood if environmental factors were taken into account. Telmo and Lousada [10] determined the caloric values of wood pellets from different wood species using a Parr 6300 bomb calorimeter. They proposed a correlation between the lower heating value and the moisture content of the wood pellets.

In this work, the functional correlation between caloric value and wood properties was derived based on the experimental values. An ANN model was also used to estimate the caloric values for different wood samples.

Experimental Measurement

An Autobomb calorimeter and the Standard Test Method for Heat of Combustion outlined in ASTM D240 were used to determine the caloric value of the wood samples. The reference data regarding the wood density were collected from the literature available from the Forestry Department of the Government of Brunei Darussalam [11]. The ash content was determined according to the Technical Association of the Pulp and Paper Industry (TAPPI) standard T 211 om-85 [12]. During the experiment, a total of 16 wood samples were used. First, nine samples were collected from the Brunei tropical forest [13,14], and the other seven samples were collected from Indian firewood [15]. These wood samples were weighed before they were placed in a furnace at 575°C for 4 h.

The samples were weighed in a tin capsule and combusted in a furnace at 11,500°C. Then, a conductivity detector was used to measure the evolved gas and to determine the composition. In this study, the wood density, caloric value, carbon content, nitrogen content, sulfur content, and ash content were determined. The botanical names and the measured properties of different wood samples are shown in Table 1.

Results and Discussion

Functional Relationship

To derive a functional relationship between the caloric values of different wood samples and the corresponding wood density values, two steps were used. During the first step (Table 1), the measured caloric values were plotted as a series of data points for each of the corresponding wood density values, as shown in Fig. 1.

During the second step, the curve fitting process was performed to construct the curve (solid line in Fig. 1) that provided the best fit for the series of data points plotted previously. Based on the curve fitting results, the relationship between the wood density (ρ) and the caloric value (cv) with a maximum determination of coefficient of 61.92% was found to be:

$$cv = -7e^{-7}\rho^3 + 0.0016\rho^2 - 1.1486\rho + 282.72 \quad (1)$$

Fig. 1 shows that the caloric values decrease sharply with the increase in density from 400 to approximately 600 kg/m³. Between 600 and 900 kg/m³, an increasing trend in the caloric values is observed, and again the caloric value decreases beyond this density point. Therefore, it is necessary to further investigate the other components of combusted wood. Using the same two-step method, the caloric values with respect to the percentage of carbon released by the combusted wood samples are shown in Fig. 2.

Fig. 2 shows that the caloric value increases with an increase in the carbon percentage, and it reaches a maximum value of the 22.51 MJ/kg at a carbon count of 44.4%. Further increases in the carbon percentage result in decreases in the caloric value. The increasing trend of the caloric value with the increase in the carbon percentage can be explained logically because carbon is one of the main contributors to the caloric value. However, the decreasing trend needs to be further investigated by considering the other components of the combusted wood samples.

The relationship between the caloric value (cv) and the carbon percentage (C) with a correlation coefficient of 69.21% is:

$$cv = -0.0703C^2 + 6.1835C - 113.84 \quad (2)$$

It has been found that the relationship between the cv and the amount of carbon has been found [16] by assuming a linear relationship as follows:

$$cv = 0.4065C \quad (3)$$

Using the same assumption, the present investigation has the following relationship:

$$cv = 0.3755C \quad (4)$$

The results of the present investigation are very similar to the previous results.

In Fig. 3, the caloric value for each wood sample is plotted with respect to the corresponding sulfur content of the combusted wood sample.

Table 1 Wood sample properties

Scientific name	Density (kg/m ³)	Caloric value (MJ/kg)	Ash (%)	C (%)	N (%)	S (%)	Reference
<i>Agathis borneensis</i> (Ab)	480	18.42	0.45	46.58	0.10	0.10	[13]

<i>Shorea</i> species (Ss)	1010	11.55	0.63	46.38	0.41	0.04	[15]
<i>Rhizophora apiculata</i> (Ra)	820	15.00	1.09	34.42	0.12	0.04	
<i>Shorea parvifolia</i> (Sp.)	405	32.26	0.35	46.89	0.13	0.008	
<i>Acacia nilotica</i>	978	23.40	2.8	46.6	0.39	0.143	[15]
<i>Acacia leucophloea</i>	967	22.51	2.7	44.4	0.43	0.092	
<i>Prosopis cineraria</i>	942	21.93	2.5	43.3	0.38	0.140	
<i>Tectona grandis</i>	889	21.68	2.2	41.2	0.41	0.099	
<i>Cassia fistula</i>	847	21.64	1.6	39.8	0.37	0.087	
<i>Butea monosperma</i>	789	20.49	1.8	38.6	0.40	0.159	
<i>Sterculia urens</i>	686	19.70	1.4	37.8	0.47	0.163	

Fig. 1 Caloric value versus density.

Fig. 2 Caloric value versus percentage of carbon.

Fig. 3 shows that the caloric value is 32.26 MJ/kg for a sulfur content of 0.005%. This value decreases sharply with the increase in sulfur content and reaches a minimum value of 14.6 MJ/kg at a sulfur content of 0.06%. After that, it increases and reaches a maximum value of 23.4 MJ/kg. Further increases in the sulfur content decreases the caloric value. It is interesting to note that the trends of **Figs. 1** and **3** are similar. Therefore, a curve between the wood density and the sulfur content was attempted, and it was found that there was less of a correlation between these two properties. With a maximum correlation coefficient of 57.12% between the caloric value (cv) and the sulfur percentage (S), the relationship between these two quantities has been found to be:

$$cv = -37443S^3 + 10903S^2 - 889.75S + 37.056 \quad (5)$$

The caloric values versus the percentage of ash produced by the combusted wood samples are plotted in **Fig. 4**.

Fig. 4 shows that the caloric value decreases as the ash content increases. It reaches a minimum value of 11.55 MJ/kg at an ash content of 0.63%. Then, it increases slowly with an increase in the ash content. The correlation between the caloric value (cv) and the percentage of ash (A) content with a maximum determination of coefficient of 49.72% is:

$$cv = -9.2927A^3 + 49.956A^2 - 66.296A + 42.225 \quad (6)$$

Fig. 3 Caloric value versus percentage of sulfur.

Fig. 4 Caloric value versus percentage of ash.

ANN Modeling

Estimation of the caloric value has been performed using a multi-layer, feed-forward, back-propagation paradigm of the artificial neural network (ANN) based on five input parameters (wood density, ash content, carbon, nitrogen, and sulfur content of evaluated sawdust species). The ANN model used here is a supervised learning method based on the generalization of the least mean square error (LMS) algorithm. It uses the gradient descent method to minimize the cost function, which is the mean square difference between the target and actual net output. To estimate the caloric value, the input parameters were first normalized between 0 and 1 so that appropriate activation functions could be used. There were seven cases available with five input parameters and one output. The network was designed using five input neurons and one output neuron, as shown in [Fig. 5](#).

Different numbers of hidden layers and hidden layer neurons were tested. A general ANN with N input layer neurons, one hidden layer with M neurons, and an output layer with O neurons can be represented as N - M - O architecture. In this study, with five input layer neurons and one output layer neuron, one-layer ANN and two-layer ANN with different numbers of hidden layer neurons (2, 5, 10, 15, 20) were tested. The *tansig* and *logsig* activation functions were used in hidden and output layers, respectively, and the output of each layer was calculated by using [Eqs. \(7\) and \(8\)](#).

$$\text{Output}_{\text{hidden}} = \text{TanSig} \left(\sum_{i=1}^P \text{input}_{h,i} \times w_{h,i} + b_h \right) \quad (7)$$

where

$\text{Output}_{\text{hidden}}$: output of the current hidden layer unit h .

Fig. 5 ANN structure.

Table 2 ANN architecture with coefficient of determination for single hidden layers

ANN architecture	Mean coefficient of determination (R^2) (%)
5-2-1	87.74
5-5-1	86.95
5-10-1	58.63
5-15-1	36.90
5-20-1	5.21

P : either the number of units in the previous hidden layer or the number of network inputs.

$\text{input}_{h,i}$: an input to unit h from either the previous hidden layer unit i or the network input i .

$w_{h,i}$: the weight modifying the connection either from unit i to unit h or from input i to unit h .

b_h : bias for unit h .

Similarly, the output of the output layer can be calculated as

$$\text{Output}_{\text{hidden}} = \text{LogSig} \left(\sum_{i=1}^P \text{input}_{h,i} \times w_{h,i} + b_h \right) \quad (8)$$

where

$\text{Output}_{\text{out}}$: output of the current hidden layer unit h .

P : number of units in the previous hidden layer.

$\text{input}_{h,i}$: an input to unit h from the previous hidden layer unit i .

$w_{h,i}$: weight modifying the connection from unit i to unit h

b_h : bias for unit h .

The TanSig and LogSig activation functions are defined as follows:

$$\text{TanSig}(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}} \quad (9)$$

$$\text{LogSig}(x) = \frac{1}{1 + e^{-x}} \quad (10)$$

The weights for the connections were initially randomly assigned and the learning rate (η) was set to 0.1. The ANN were trained and validated using the leave one out cross-validation (LOOCV) method, whereby one observation from the sample is used as validation data and rest of the observations are used for training the network. This process was repeated 10 times for each case and a mean coefficient of determination (R^2) was computed for each architecture. The coefficient of determination (R^2) for the architecture of each single layer of hidden network is shown in [Table 2](#).

The training/testing results of single hidden layers with different numbers of neurons are shown in [Figs. 6–10](#).

Similarly, the coefficients of determination (R^2) for each two-layer hidden network architecture are shown in [Table 3](#).

Fig. 6 Training and testing of 5-2-1 ANN architecture.

Fig. 7 Training and testing of 5-5-1 ANN architecture.

Fig. 8 Training and testing of 5-10-1 ANN architecture.

Fig. 9 Training and testing of 5-15-1 ANN architecture.

Fig. 10 Training and testing of 5-20-1 ANN architecture.

Table 3 ANN architecture with coefficient of determination for two hidden layers

ANN architecture	Mean coefficient of determination R^2	ANN architecture	Mean coefficient of determination R^2
5-2-2-1	30.69	5-10-15-1	46.78
5-2-5-1	32.12	5-10-20-1	42.28
5-2-10-1	69.11	5-15-2-1	44.98
5-2-15-1	73.24	5-15-5-1	31.26
5-2-20-1	48.47	5-15-10-1	61.98
5-5-2-1	33.18	5-15-15-1	73.69
5-5-5-1	58.33	5-15-20-1	85.85
5-5-10-1	55.65	5-15-25-1	84.86
5-5-15-1	82.45	5-20-2-1	35.79
5-5-20-1	71.56	5-20-5-1	46.16
5-5-25-1	74.32	5-20-10-1	44.38
5-10-2-1	47.66	5-20-15-1	52.29
5-10-5-1	48.89	5-20-20-1	63.36
5-10-10-1	68.51	5-20-25-1	73.01

For single hidden layers of the ANN, the maximum value of R^2 of 87.74% was found for 5-2-1 architecture. Table 2 shows that the value of R^2 decreased as the number of neurons in the hidden layer increased. However, for ANN architecture with two hidden layers, the maximum value of R^2 was found to be 85.85% for 5-15-20-1. In general, no advantage could be achieved using the ANN with two hidden layers.

Conclusion

Functional relationships between the caloric value and wood density, carbon content, sulfur content, and ash content have been derived from the experimental data collected from 16 different wood samples from Brunei Darussalam. To validate the experimental findings, an ANN model considering five input parameters with a single hidden layer and two hidden layers was used. In the ANN model, a multi-layer, feed-forward, back-propagation paradigm is used. For a single hidden layer, the coefficient of determination (R^2) was found to be 87.74% for 5-2-1 architecture. However, with two hidden layers in the 5-15-20-1 ANN architecture, R^2 was found to be 85.85%. There was no advantage to using ANN architectures with two hidden layers, but the results and high R^2 values validate the experimental findings. Using these results it can be concluded that the wood and wood by-products from Brunei Darussalam can be used efficiently as good, renewable energy resources.

Introduction

Additive manufacturing (AM), commonly known as three-dimensional (3D) printing or rapid prototyping has been commercially introduced in late 1980s. Although a considerable amount of progress has been made in this field, still lot of research work needs to be done in order to overcome the various challenges remained (Khoo *et al.*, 2015). Among the major advances that this process presented to product development are the time and cost reduction, human interaction, and consequently the product development cycle (Wong and Hernandez, 2012), also the possibility to create almost any shape that could be very difficult to machine. However, at the present time it is not yet adopted in the manufacturing sector, but scientists, medical doctors, market researchers and artists use it extensively (Flowers and Moniz, 2002; Noorani, 2006). With AM, scientists can rapidly build and analyse models for theoretical comprehension and studies. Doctors can build a model of a damaged body to analyse it and plan better the procedure, market researchers can see what people think of a particular new product, and rapid prototyping makes it easier for artists to explore their creativity (Cooper, 2001).

Today, various AM machines/setups are found not just in industry but in households, as the price of 3D printers has fallen below US\$1000. One can print almost anything, which opens up unlimited opportunities for us to manufacture toys, household appliances and tools in our living rooms (Raviv, 2014a,b). Thermoplastics, metal powders, photopolymers and ceramic powders are some important and useable materials for AM process (Tofail *et al.*, 2017).

AM processes take the information from a computer-aided design (CAD) file that is later converted to a stereo lithography (STL) file. In this process, the drawing made in the CAD software is approximated by triangles and sliced containing the information of each layer that is going to be printed (Wong and Hernandez, 2012).

Fig. 1 shows classification of AM processes broadly as liquid base, solid based, and powder based. The processes included in this are considered the most relevant in the past, and promising for the future of the industry (Kruth, 1991).

The polymeric component by AM can be better alternatives in the following manners (Ligon *et al.*, 2017):

- Cost effective;
- Produced lightweight component;
- Ease of fabricate the parts;
- Better dimensional manipulations;
- Requirement of low temperature for production etc.

But there's more that can be done with 3D printed materials to make them more flexible and more useful for example the structures that can transform in a pre-programmed way in response to a stimulus. Recently given the popular name of "4D printing", perhaps a better way to think about it is that the object that transforms over time (Mouzakis, 2018).

Basics of 4D Printing

4-dimensional printing uses the same techniques of 3D printing through computer programmed deposition of material in successive layers to create a three-dimensional object. However, 4D printing adds the dimension of transformation over time (Tibbitts, 2014). It is therefore a type of programmable matter, wherein after the fabrication process, the printed product reacts with parameters within the environment (humidity, temperature, etc.) and changes its form accordingly. The ability to do so arises from the near infinite configurations at a micrometer resolution, creating solids with highly engineered molecular spatial distributions (Li *et al.*, 2016) and thus allowing unprecedented multifunctional performance. 4D printing is a relatively latest in bio fabrication technology and rapidly emerging as a new paradigm in disciplines such as bioengineering, materials science, chemistry, and computer sciences (Le Feuvre and Scrutton, 2018).

Types of 4-D printing

4-D printing can be defined as the ability of a material to change its shape or physical properties with the passage of time, automatically and autonomously, that is, without any external intervention. Many common terms such as autonomic-4D printing and autonomic self-changing are used to define such a property in materials. Incorporation of changing in physical properties in manmade materials very often cannot perform without an external trigger. Thus, 4-Dimensional printing can be of the following two types:

- Autonomic (without any intervention);
- Non-autonomic (needs human intervention/external triggering).

Fig. 1 Three-dimensional printing processes.

Recently, one of the actively researched areas lies in the additive manufacturing of smart materials and structures. 4D printing may be defined as an additive manufacturing process that integrates smart materials into the starting form of the printing material for 3D printed structures/components. After fabrication, the 3D object would respond in an intended manner to external stimuli from the environment or through human interference, resulting in a change in shape or physical properties over time (Khoo *et al.*, 2015).

Smart Materials

Smart materials are those materials that have the ability to change their shape or properties under the influence of external stimuli. With the introduction of smart materials, the AM-fabricated components are able to alter their shape or properties over time (the 4th dimension) as a response to the applied external stimuli. Hence, this gives rise to a new term called '4D printing of smart materials' to include the structural reconfiguration over time (Khoo *et al.*, 2015).

Piezoelectricity

A piezoelectric material accumulates electrical charges when mechanical stress is applied. This is called piezoelectric effect, while conversion of the electric field to mechanical strain is called reverse piezoelectric effect. Before understanding various coefficients of piezoelectricity for solid piezoelectric material, the direction of material due to the anisotropic nature of piezoelectric material must first be defined. Typical piezoelectric coefficients are denoted as A_{ij} where i denoted as the direction of the electrical measurement, and j denotes the direction of the mechanical movement (Ueberschlag, 2001). Fig. 2 shows the typical dimensions of piezoelectric material for defining the piezoelectric constants.

Some of the important piezoelectric constants regarding this study are:

Piezo strain constant: d_{3j} ($C/m^2/N/m^2$) represents the piezoelectric effect in the film. This constant indicates how much charges can be accumulated in $1 m^2$ when $1 Pa$ of pressure is applied along the " j " axis. Typical values of d_{33} for PVDF and its copolymer are between 20 and 30 $C/m^2/N/m^2$.

Piezo stress constant: g_{3j} ($V/m)/(N/m^2)$ represents the electric field induced in " 3 " direction by a stress of $1 Pa$ is applied along the " j " axis. It is often called piezo voltage constant and the typical g_{33} values for PVDF polymer are around 200–300 $V/m/N/m^2$ (Bauer and Bauer, 2008; Xu *et al.*, 2009).

Electroactive Polymers (EAP)

Electroactive polymers, or EAPs, are polymers that exhibit a change in size or shape when stimulated by an electric field. A typical characteristic property of an EAP is that they will undergo a large amount of deformation while sustaining large forces (Biggs *et al.*, 2013). EAP materials can be easily manufactured into various shapes due to the ease in processing many polymeric materials, making them very versatile materials.

EAP are of two types

- (1) Dielectric EAPs are materials in which actuation is caused by electrostatic forces between two electrodes which squeeze the polymer. Dielectric elastomers are capable of very high strains and are fundamentally a capacitor that changes its capacitance when a voltage is applied by allowing the polymer to compress in thickness and expand in area due to the electric field (Anderson *et al.*, 2012).
- (2) Ionic EAPs, in which actuation is caused by the displacement of ions inside the polymer. Only a few volts are needed for actuation, but the ionic flow implies a higher electrical power needed for actuation, and energy is needed to keep the actuator

Fig. 2 Schematic representation of dimensions in piezoelectric material. Reproduced from Ueberschlag, P., 2001. PVDF piezoelectric polymer. Sensor review 21 (2), 118–126.

at a given position. Examples of ionic EAPS are conductive polymers, ionic polymer-metal composites (IPMCs), and responsive gels (Biddiss and Chau, 2006).

Ferroelectric polymers (dielectric polymers) are a group of crystalline polar polymers that are also ferroelectric, meaning that they maintain a permanent electric polarization that can be reversed, or switched, in an external electric field (Wang, 2001). Ferroelectric polymers, such as polyvinyl diene fluoride (PVDF), are used in acoustic transducers and electromechanical actuators because of their inherent piezoelectric response, and as heat sensors because of their inherent pyroelectric response (Kochervinskii, 2003).

PVDF

PVDF is lightweight, flexible, has low acoustic impedance and high piezoelectric constant, making it a good candidate for acoustic or biomedical sensors. The crystallinity of the PVDF polymer will be a major factor on the piezoelectric constant of polymers (Xu *et al.*, 2009). Typical piezoelectric polymers have a crystalline region that has an internal dipole moment. These dipole moments are randomly oriented without any mechanical or electrical poling process (Sencadas *et al.*, 2009), and the net dipole moment is zero in this condition. This type of structure is called α -phase PVDF film that has no piezoelectric response. The α -phase PVDF film is commonly used as insulating material because of its low thermal conductivity, low density, and high chemical and heat resistance. With post processes such as mechanical stretching and electrical poling under a high electric field, crystalline regions inside the bulk PVDF film will align in electric field direction (Kim and Arias, 2015). The PVDF structure with this morphology is called β -phase film. It has been shown that the higher β -phase portion of PVDF film shows a higher piezoelectric constant as sensor material. Typically, around 90%~95% of β -phase portion shows a strong piezoelectric response for PVDF polymer (Satapathy *et al.*, 2008). Copolymers of PVDF such as PVDF tetra fluoro ethylene (PVDF-TrFE) show higher crystallinity due to its chemical structure, resulting in better piezoelectric response. Upon application of post processes to the PVDF film, the β -phase PVDF film retains its morphology unless there are severe changes in temperature to the film. The maximum operating temperature for the β -phase PVDF film is 80°C and 110°C for the β -phase PVDF-TrFE film (Kim and Arias, 2015).

Table 1 shows the material property of common piezoelectric materials.

Piezoelectricity in Semi Crystalline Polymers

A PVDF film without any post processes such as mechanical stretching or electrical poling results in the alpha phase PVDF structure that has a zero net dipole moment in the crystalline region, as shown in Fig. 3. This type of crystalline structure has no piezoelectric characteristic, because the α -phase PVDF crystalline regions will align such that all dipole moments cancel each other. On the other hand, the β -phase PVDF structure of PVDF has Fluorine on the one side and Hydrogen on the other side, as shown in Fig. 4. This will form a net dipole moment in a stacked direction inside the β -phase PVDF crystalline regions. When stress is applied to this stacked polymer chain region, it will change the local dipole distributions and induce an electric field in the stack. The induced electric field accumulates the charges at both the top and bottom of the film, demonstrating the principle of piezoelectric effect. Various studies show ways to increase the β -phase portion in the film by mechanical or electrical poling (Lau *et al.*, 2013). A copolymer of PVDF, PVDF-TrFE, shows a higher temperature range of use, a slightly higher piezo strain constant, and a higher portion of β -phase morphology with just thermal annealing process (Wang *et al.*, 2015). PVDF-TrFE is a good candidate material for piezoelectric polymer sensor because it can achieve high portion of β -phase morphology without poling process.

Barium titanate

Barium titanate is the inorganic compound with the chemical formula BaTiO_3 . Barium titanate is a white powder and transparent as larger crystals (Veith *et al.*, 2000). This titanate is a ferroelectric ceramic material, with photorefractive effect and piezoelectric properties. It is used in capacitors, electromechanical transducers and nonlinear optics (Xu, 2013).

Graphene

Graphene is an allotrope of carbon having single layer sp^2 hybridization arranged in a two-dimensional hexagonal lattice. It is the basic structural element of many other allotropes of carbon, such as graphite, diamond, charcoal, carbon nanotubes and fullerenes

Table 1 Material property of common piezoelectric materials

Material property	Units	PVDF	Nylon 11	PVC	PZT	Barium titanate
Density	g/cm ³	1.78	1.15	1.45	7.5	5.7
d ₃₁ piezoelectric constant	pC/N	23	0.26	0.7	1200	1700
g ₃₁ voltage constant	Vm/N	216	2.5	6.6	10	5
Acoustic impedance	106 kg/m ² s	2.7	2.9	3.27	30	30

(Neto *et al.*, 2009). Graphene has many unusual properties. It is the strongest material ever tested. The material has been of intense interest because of its mechanical, thermal, and electrical properties (Zhang *et al.*, 2010).

Twin-Screw Extrusion (TSE)

The TSE process was started by 'Clextral', over 20 years back, for continuous production of exceedingly uniform and finely structure components. It is generally used to deliver bio-sourced plastics, fabrication of feed stock filament, and reinforcement of polymers with fillers or ceramics. Fig. 5 demonstrates the schematic of TSE process.

The primary purpose of TSE processing is blending of the at least two materials equally and producing a good quality components/parts with precise control of process conditions. There are extensive variety of barrel and screw plan, different process capacity and screw profile to be set up as indicated by requirements of process. Twin-screw extruders are competent to guarantee blending, shearing, cooling, warming, compacting, molding, and so forth with abnormal state of adaptability. The fundamental points of interest of twin-screw extruders (intermeshing co-turning) are their uncommon blending capacity that gives the amazing qualities to expelled items. In TSE process, the crude materials could be solids (granules and powders form) or fluids (Dombe *et al.*, 2015).

Literature Review

3D Printing

Li *et al.* (2002) worked for fabrication of ABS based FDM Prototypes with Locally Controlled Properties deposition density and deposition orientation and make a comparison between the theoretical and experimental analysis. They observed that the parts fabricated at raster angle 45/-45 having minimum young's modulus as compare to parts fabricated at 0/90 raster angle having maximum young's modulus and also there is a difference between the theoretical and experimental outcome values.

Fig. 5 Schematic of TSE techniques. Singh, R., Sandhu, G.S., Penna, R., Farina, I., 2017. Investigations for thermal and electrical conductivity of ABS-graphene blended prototypes. *Materials* 10 (8), 881.

Upcraft and Fletcher (2003) compared various rapid prototyping technologies including stereo lithography, selective laser sintering, fused deposition modeling, laminated object manufacturing, three-dimensional printing and multi-jet modeling. It also covers surface roughness considerations and mechanical properties including dimensional accuracy and compares costs of various systems. They concluded that in the case of FDM when the raster angle was increased from 10° , 20° up to 90° , the surface roughness of the fabricated model was decreased. The dimensional accuracy FDM parts were 97% when compared to CAD data. The FDM is cost effective way to produce 3D structures as compared to other RP techniques.

Modeen (2005) highlighted that the file generated in CAD model could be easily converted into layer fabricating files. The strong point of layer depositing technique is its capability to create the mirror image of CAD design.

Novakova-Marcincinova *et al.* (2012) shared the data about progress and normal accessible materials that are utilized for item fabricating by FDM. i.e., a RP innovation. While utilizing diverse innovation of fast model the primary condition of item material might be accessible in many shape. There can be fluid, powder shape or solid form. It can be also accessible in different types of solids like wire, laminates or beds. The material utilized as a part of this exploration paper incorporates nylon, paper, resin wax, ceramics. In FDM be materials that is utilized are ABS, polypropylene, polyamide and polyethylene. some extraordinary materials are utilized in the FDM system are nitrile, hydroxyapatite, silicon, stainless steel, PZT and Al_2O_3 .

Romero *et al.* (2015) compared the 3D printed product with the conventional master cast and also studied the material consumption and cost occurred in both processes. It was concluded that Rapid manufacturing produced the best fit parts with negligible material wastage when compared to conventional manufacturing class. The results also show the saving of cost in RP process.

Torres *et al.* (2015) optimized the process parameters' of FDM (infill percentage, layer thickness and post heat treatment on the mechanical strength of the prototypes ANOVA was used for optimization process. They concluded that the layer thickness and infill percentage has more effects on the mechanical strength. Whereas the post heat treatment (at three different time intervals 0–20 mins)) affects the mechanical strength of less dense part only.

Singh *et al.* (2017) studied that the reinforcement of graphene in ABS polymer matrix can be directly printed with an open source 3-d printer and graphene is responsible for enhance the electrical and thermal conductivity of the ABS polymer.

Lin *et al.* (2015) demonstrated the first three-dimensional (3D) printed graphene complex structures by stereolithography with good combination of strength and ductility. With only 0.2% GOs and found that, the tensile strength is increased by 62.2% and elongation increased by 12.8%.

Dul *et al.* (2016) fabricated 3d parts with graphene nanoplatelets (xGNP) reinforcement into ABS. It has been found that, there is a decrease in both stress and strain at break was observed when xGNP is added to ABS. Moreover, a higher thermal stability was induced on 3D printed parts by xGNP, as indicated by a reduction in both coefficient of linear thermal expansion and creep compliance.

4D Printing

Polyjet printing and syringe printing are the most popular forms of 4D printing, but other 3D printing technologies such as FDM, SLS, and stereo lithography are processes that could be incorporated in 4D printing technology; however, some 4D printing technologies may require multi-materials and multiple nozzles, which limits what 3D printing methods can be used. Exploring different printing methods may allow for different smart materials to be 3D printed that are stronger, lighter, induce different property changes, and react to different stimuli.

According to Pei (2014), 4D printing is the process of building a physical object using appropriate additive manufacturing technology, laying down successive layers of stimuli-responsive composite or multi-material with varying properties. After being built, the object reacts to stimuli from the natural environment or through human intervention, resulting in a physical or chemical change of state through time.

Tibbitts *et al.* (2013) stated 4D printing as a new process that 'entails multi-material prints with the capability to transform over time, or a customised material system that can change from one shape to another, directly off the print bed' with the fourth dimension described here as the transformation over time, emphasising that printed structures are no longer static, dead objects; rather, they are programmably active and can transform independently.

Zhou *et al.* (2015) outlined that rigid materials can be 3D printed along with smart materials to create specific areas of a part that act as joints and hinges for bending. This process of 3D printing parts that change shape over time when exposed to an external energy has been termed 4D printing by Skylar Tibbitts from Massachusetts Institute of Technology (MIT).

Leist and Zhou (2016) highlighted the onset of multi-material 3D printing and the combination of smart materials into the printable material has led to the development of an exciting new technology called 4D printing. This paper will introduce the background and development into 4D printing, discuss water reactive 4D printing methods and temperature reactive 4D printing, modeling and simulation software, and future applications of this new technology. Smart materials that react to different external stimuli are described, along with the benefits of these smart materials and their potential use in 4D printing applications; specifically, existing light-reactive smart materials. 4D printing has the prospective to simplify the design and manufacturing of different products and the potential of automating actuation devices that naturally react to their environment without the need for human interaction, batteries, processors, sensors, and motors.

Tibbitts (2012) highlighted that construction must be made smarter and solve the problems of wasting large amounts of energy, materials, money, and time for building. These issues can be solved using design programs and software to embed information into the materials that makes the material and construction more accurate. At the beginning, Tibbitts proposed a process called self-assembly, which uses small units that form larger structures when exposed to external energy.

Tibbitts *et al.* (2011) outlined that self-assembly may be applied to 1D strands forming organized 2D and 3D shapes, along with 2D planar shapes forming 3D objects. Self-assembly may not be efficient for every purpose, which means different sectors and applications must be identified that benefits most from self-assembly.

A market research report predicts that the 4D printing industry could be worth \$63.00 million in 2019 and \$555.60 million in 2025 (Markets and Markets, 2015). The market report predicts that 4D printing may find applications in the automotive, textiles, construction, healthcare, utility, aerospace, and military industries. It is predicted the defense and military sector would have the largest share, followed by the aerospace industry. These are just a minor number of application ideas for 4D printing that reflect a number of 3D printing methodologies and activation energies. This paper presents the current research focused on 4D printing methods, smart materials that allow for its activation, and the future applications for this exciting innovative technology.

Smart Materials

Developments in 4D printing

In this section, some developments of 4D printing that exhibit physical changes of the printed components/ structures are illustrated. They are classified according to whether they are printed with a combination of multiple materials or with a single material.

4D printing with single material

In this section, 4D printing of either a single smart material or a mixture of smart material and conventional material as the starting form for printing has been detailed.

Kim *et al.* (2017) proposed an integrated 3D printing process with corona poling to fabricate piezoelectric PVDF sensors without post poling process. This proposed process, named 'Integrated 3D Printing and Corona poling process' (IPC), uses the 3D printer's nozzle and heating bed as anode and cathode, respectively, to create poling electric fields in a controlled heating environment. The nozzle travels along the programmed path with fixed distance between nozzle tip and sample's top surface. Simultaneously, the electric field between the nozzle and bottom heating pad promotes the alignment of dipole moment of PVDF molecular chains. The crystalline phase transformation and output current generated by printed samples under different electric fields in this process were characterized by a Fourier transform infrared spectroscopy (FTIR) and through fatigue load frame. It is demonstrated that piezoelectric PVDF films with enhanced β -phase percentage can be fabricated using the IPC process.

Kamila (2013) outlined that the printed components consisting of a single smart material or a mixture of smart and conventional materials, the smartness of the materials plays a more important role in achieving the intended response than in the case of a multi-material component. The smartness of the smart materials or mixtures describes the self-adaptability, self-sensing, shape memory, decision making and multiple functionalities of the materials or mixtures.

Kim *et al.* (2014) stated those characteristics that determined how the printed components change their properties in response to the external stimulus and they provide various promising applications of these materials. In the following, recent developments of 4D printing that consist of either a single smart material or a mixture of materials as the starting form will be highlighted, including enhanced smart nanocomposites and 3D printing of SMPs.

Dadbakhsh *et al.* (2014) studied the effect of SLM process parameters on the transformation temperature of fabricated parts Nickel titanium and found that SLM restores the 0.5% SME in the fabricated structure. SLM process eliminates the inhomogeneity of starting powder

Rossiter *et al.* (2009) fabricated thin membrane with a thick circular collar (thickness of the central membrane was approximately 90 μm) of acrylic-based photopolymer by PolyJet and found that thin membrane produces large strains upon activation by electricity. Thus it demonstrated that 3D printing have potential to produce electroactive actuators.

Bodkhe *et al.* (2017) demonstrated the production of 4 V from a 3d printed sensor of PVDF reinforced with BaTiO_3 . The 3d scaffolds were fabricated with Solvent evaporation-assisted 3D printing process and were able to stabilize the β -phase at room temperature.

Enhanced smart nano-composites

Uchino (2017) highlighted one important type of smart material that has been used widely is the piezoelectric material that is able to produce electrical charge or voltage when experiencing an externally applied stress and vice versa. Different categories of piezoelectric materials offer different capabilities.

Kim *et al.* (2014) stated that piezoelectric polymeric materials have some unique characteristics as compared to other piezoelectric materials. These materials are suitable for systems that require mechanical flexibility, small active elements, biocompatibility and solution-based processability. However, it is still a difficult task to fabricate piezoelectric polymeric materials into complex 3D structures or small active elements. Thus, further improvement in the manufacturability of piezoelectric polymers will definitely have a huge contribution to the development of various applications which require micro-scale and nano-scale piezoelectric polymers, such as biodiagnostic devices, micro-scale and nano-scale electromechanical systems, imaging systems, compact sensor designs and electronics.

4-D printing of multiple materials

Raviv *et al.* (2014a,b) found an important factor to consider when designing a component with multiple materials is the availability of the 3D printing technology. Moreover, in the developments of 4D printing of multiple materials, the design of the components plays a critical role as the conventional materials do not react to the external stimulus. Hence, the degree of the change in the printed components upon activation is usually determined by the design of the components. In order to illustrate this point, some examples of the developments in 4D printing of multiple materials are discussed. These examples include printed actuators for soft robotics, self-evolving structures, anti-counterfeiting system.

Srivastava *et al.* (2010) stated another class of smart materials that are gaining popularity are shape memory polymers (SMPs). SMPs possess the ability to remember a permanent shape and transform to a temporary shape when exposed to a number of external stimuli such as temperature,

Hager *et al.* (2015) studied that SMP could create products that react to their environment automatically without the need for complex, heavy, and expensive electronic actuation systems. Some other smart materials, called self-healing materials, that possess the ability to react to external stimulus and repair themselves, which may prove useful for devices exposed to extreme environments.

Gladman *et al.* (2016) at Harvard's School of Engineering and Applied Sciences (SEAS) were capable of 3D printing a single smart material using a syringe nozzle and photo polymerization of their smart material for their 4D printing research.

Lendlein, (2010) stated that smart materials are essential to the development of 4D printing research. There are many smart materials in development; however, not every smart material can be 3D printed. Also, smart materials do not need to possess shape change in order to be important to 3D printing research. Materials that possess the ability to change color, hardness, or transparency may become important in camouflage technology, signaling for users, detecting foreign substances, and biomedical applications.

Ge *et al.* (2013) created a 4D printing technique that uses a combination of heat and stress to activate a shape memory composite to bend at different rates and directions depending on the design of the hinges. Glassy polymers in the form of fibres exhibit shape memory effects (SMEs) when heated above their glass transition temperature (T_g) and are 3D printed within an elastomeric matrix combination of elastomer and glassy polymer fibres creates a soft composite, which the team has named printed active composites (PACs).

Mao *et al.* (2015) were successful in implementing their 4D printing techniques for the creation of self-assembling origami structures: A box, pyramid, a three hinged airplane, and a five hinge airplane. A box with the six rigid sides connected by PAC hinges is 3D printed in a flat shape. The PAC hinges are pre-programmed with definitive bending angles using the relation of PAC hinge length and applied strain to determine the bending angle. The walls of the box should bend at a 90° , so the hinges required a strain of 20% to be applied while the material is heated above its glass transition temperature (T_g), cooled, then releasing the prestrain. The component managed to form the box shape with minor irregularities due to inconsistencies when straining the material (see Fig. 6(a and b)).

Ge *et al.* (2014) found that the inclusion of smart materials in their 3D printing components could save time and material. 3D printing a 20 mm $\times$ 20 mm $\times$ 20 mm hollow cube with a wall thickness of 1 mm could take 10 minutes when printed in a flat 2D shape then activated to become a 3D cube. However, direct 3D printing a cube with the same dimensions takes 3 h to print and post processing of removing support material can take numerous hours.

Kravchenko *et al.* (2011) found that light is an effective activation technique because it is an abundant source of energy, wireless, and controllable. However, it can be difficult to transform light energy into mechanical energy for use in SMPs. Light-activated SMPs have been used in areas of self-assembly structures, complex folding methods, transformative surface deformations.

Based on literature review, following gaps have been identified:

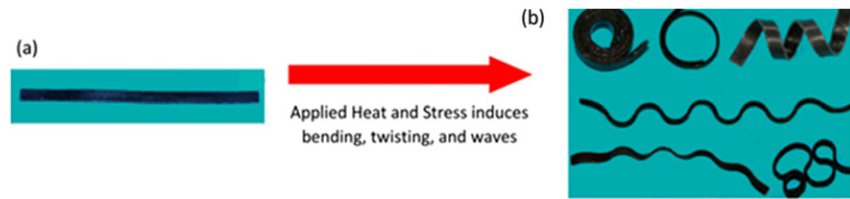

Fig. 6 (a) Initial flat shape of PAC without heat activation. 6(b) Flat PAC material displays bending, twisting and wave shape changes when heat and stress is applied depending on the orientation of the PAC fibre.

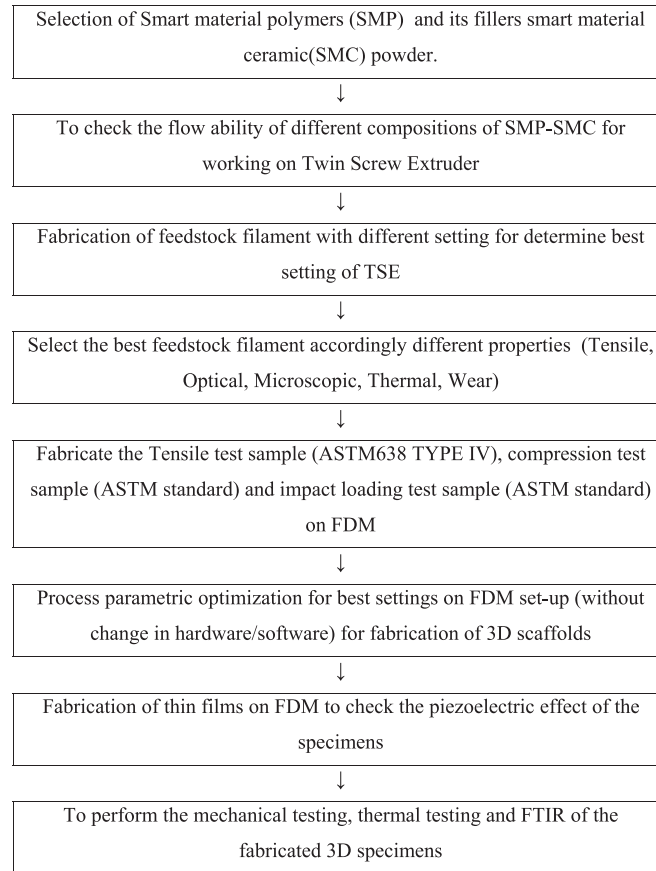

Fig. 7 Flow chart for detailed methodology.

- It has been observed that many researchers have been worked in the field of 3D printing of commercially available materials only, but very few have reported the 3D printing of EAP matrix for 4D applications. Since 4D printing is upcoming field in AM, not much data has been reported regarding the 4-D printing with fused deposition modeling (FDM) which is one of the low cost AM technique.
- Smart materials are used in actuators, sensors applications and can be fabricated by conventional manufacturing processes as well as by 3D printing. Some of the commonly reported smart materials are PVDF and BaTiO₃. Still no work has been reported for preparing 4D printed parts by using PVDF, Gr and BaTiO₃ with FDM process.

Proposed Methodology/Frame Work for 4D Applications

The detailed methodology for 4D printing applications is shown in form of block diagram (see Fig. 7).

Summary

In this article detailed procedure has been outlined for preparing different proportions of BaTiO₃, Gr reinforced PVDF matrix for 4D printing applications. Commercially for preparing FDM feed stock filament (for open source 3D printer) of BaTiO₃ and Gr

reinforced PVDF mechanical mixing with twin screw extruder/chemical mixing may be used. The future studies may be focused on detailed rheological (melt flow index), thermal analysis of feed stock filaments prepared by using (mechanical/chemical mixing) and there is strong need to perform parametric optimization of feedstock filament wire (prepared by mechanical/chemical mixing), based upon mechanical and metallurgical testing (tensile test, scanning electron microscope) for final selection of feed stock filament for 3d printing. Finally parametric optimization from mechanical/piezoelectric properties view point needs to be performed for printed functional prototypes on FDM.

Introduction

Fiber reinforced resins, thermosets as well as thermoplastics, are increasingly used to replace metals in a number of industrial, sporting, and transport applications. One of the biggest challenges posed by fiber reinforced composites is their recycling. Environmental legislation is becoming more and more restrictive, and just the environmental impact of these materials disposed in landfills is accelerating the urgency to reach more industrial scale solutions to the recycling of composites. Landfill is a relatively cheap disposal route but is the least preferred waste management option (Jacob, 2011; Oliveux *et al.*, 2015; Bos, 2002; European Union, 2008). Polymeric waste materials should be considered resources for the manufacture of new products through recycling processes, with a similar status to virgin fossil-based plastics and biopolymers from renewable resources (Vilaplana and Karlsson, 2008). In the case of high impact polystyrene (HIPS), thermooxidative degradation affects more severely than multiple processing the long-term stability and properties; degradation during service life seems therefore to determine the further possibilities of employing HIPS recyclates in second-market applications (Vilaplana and Karlsson, 2008). Other synthetic plastics such as polyolefins (high-density polyethylene (HDPE) and PP) and PET are more affected by thermomechanical degradation by multiple processing than they are by thermooxidative aging, indicating that special attention should be focused on controlling the processing conditions during mechanical recycling (Vilaplana and Karlsson, 2008; Badia *et al.*, 2017). Polymers suffer chemical and physical changes during their processing and service life. They undergo oxidative reactions at every stage of their life cycle, and the new functional groups formed during the oxidation process may enhance the sensitivity of the recyclates to further thermal and photodegradation (Vilaplana and Karlsson, 2008). Various researchers have used different methods for recycling of the polymers by using the various kind of fillers or reinforcement to increase their life cycle and application domain (Singh *et al.*, 2016).

Materials

Nowadays, investment casting is basically used to prepare complex parts with high accuracy by using wax as pattern. The polymeric parts produced by additive manufacturing (AM) technology can be used for prototypes, sacrificial patterns for investment casting, and even they can be used as functional prototypes. In addition to industrial polymers, biocompatible polymers, such as poly-ε-capro-lactone (PCL) and polyetheretherketone (PEEK) and starch-based polymers, also have been investigated by many researchers with selective laser sintering (SLS), fused deposition modeling (FDM) and other commercial 3-dimensional printing (3DP) processes for biomedical applications such as implants and tissue scaffolds (Schmidt *et al.*, 2007; Leong *et al.*, 2007; Ramanath *et al.*, 2008; Ramanath *et al.*, 2007; Lam *et al.*, 2002). Metal parts can also be produced by using rapid casting (RC) by combining AM produced patterns, or casing shells and cores, and subsequently casting with molten metal, such as investment casting and sand casting (Cheah *et al.*, 2005). Casting patterns built using AM processes were also applied to investment casting, such as polymer patterns via stereo lithography (SLA), wax patterns via FDM, paper patterns via laminated object manufacturing (LOM), polymer patterns via 3DP and SLS. Other AM processes, such as SLA, FDM and 3DP, can fabricate metal parts (like turbine blades) for aerospace applications by building casting patterns for investment casting. Integrally cored ceramic molds for investment casting of turbine blades have been fabricated using ceramic stereo lithography (Bae, 2008), and as well as by gel casting ceramic slurry into plastic molds made from SLA patterns (Wu *et al.*, 2009a,b). The shortcomings of the traditional investment casting are a complex process, a long manufacturing time, high cost, and that they pose the bottleneck of pattern making (Feng and Zhang, 1999). In today's competitive environment, the manufacturing industries are striving for development of next generation products due to increasing competition among the products and continuously changing customer needs. Among the challenging tasks the manufacturers are facing include increasing product complexity. This has emerged the concept of rapid physical realization of products well before its manufacturing (Ingole *et al.*, 2009). The cost of WAX pattern making with the help of conventional investment casting method is costlier than the ABS pattern making in FDM. The use of benefits in terms costs have proved that the adoption of AM technology is technoeconomically justifiable for the Indian manufacturing industries. AM has proved to be a cost-effective and time-efficient approach for the development of pattern making, thereby ensuring the possibility for technology transfer in Indian manufacturing industries (Jauhar *et al.*, 2012). Many methods for rapid tooling (RT) have been developed so far, for the application on many production processes including injection molding (Barlow *et al.*, 1996; Masood and Song, 2004; Vasconcelos *et al.*, 2004, 2006; Ma *et al.*, 2007; Ingole *et al.*, 2009, 2002; Hsu *et al.*, 2008), investment casting (Ingole *et al.*, 2009), sheet metal forming (Colton and Park, 2003), and resin transfer molding (RTM) (Gibbons *et al.*, 2010).

The first use of AM-fabricated patterns as sacrificial patterns in traditional investment casting (IC) started in 1989 (Greenbaum and Khan, 1993). Since then all major AM techniques have been used in different casting methods to provide RC solution for producing metal parts. HDPE, being an abundantly available material, has been chosen for this purpose. HDPE is primarily used for the production of bottles especially for food products, detergents and cosmetics, containers, toys, house wares, fuel tanks and industrial wrapping and film, sheets, gas, and waste pipes. However recycled HDPE is used for producing industrial bags, detergent bottles, pipes, containers, and wood substitute, for example, animal flooring and fencing (APME, 1993). HDPE is a linear polymer with the chemical composition of polyethylene, $(CH_2)_n$, and is defined by ASTM D1248-84 as a product of ethylene polymerization with a density of 0.94 g/cm^3 or higher. Postconsumer recycled HDPE exhibits adequate process ability and a balance of physical properties adequate for a number of noncritical applications in blow molding (Ashraf, 2000). These processes usually use commodity polymers such as PVC, PS, PP, LDPE, and HDPE. The extrusion part of the process is continuous and the rest is cyclic (McCrum *et al.*, 1997). The principal types of polymers in municipal solid waste (MSW) are polyolefins (PO), consisting of polyethylene (low density or LDPE and high density or HDPE) and polypropylene (PP), polystyrene (PS), polyvinylchloride (PVC), and polyethylene terephthalate (PET) (Alter, 1993). In this article an effort has been made to prepare a metal matrix composite by using the investment casting route. Further, waste polymer, mainly HDPE and LDPE, has been selected as matrix material and some of the reinforcements, namely, SiC and Al_2O_3 , have been used as filler material.

Process

Fig. 1 shows the process flow diagram for preparation of aluminum matrix composite (AMC).

This study highlights the processing of HDPE with ceramic reinforcements, keeping the aim of preparing the final product via investment casting route. Initially, waste polymer was collected from industry and recycled for its further use. Recycling of HDPE includes extrusion through single screw. There are various methods available for recycling of polymer including primary, secondary, tertiary, and quaternary (Al-Salem *et al.*, 2009). Primary and secondary recycling includes extrusion, injection molding, and drawing. In tertiary recycling chemicals are used for processing of the polymer and in the quaternary scheme energy recovery is the main motive behind recycling (Hopewell *et al.*, 2009). This article purely concentrates on the recycling by extrusion route and further use of the delivered product in the form of wire in 3D printing applications for preparation of the patterns for investment casting. An effort has been made to develop FDM filament wire by using the waste (HDPE) as matrix material and SiC/ Al_2O_3 as reinforcements. Waste material and reinforcement were blended together in various proportions by using mini compounder and then processed by using the single screw extruder and rheological and thermal behavior was tested. After experimentation SEM analysis was carried out to ensure dispersion and structure of obtained filament wire. After getting all the results from the SEM analysis those wires were made to run in a 3D printing machine to prepare the patterns for the investment casting. Patterns made by using fused deposition modeling were then carried for the final stage of casting and layers were laid on the pattern for further step. Finally aluminum metal was poured into the sprue and castings were obtained after disposing of the outer structure of investment casting. Finally, the obtained parts were studied for their enhanced properties. The main motive of this work was to prepare a functionally graded material having presence of the reinforcements that were added to the HDPE.

Fig. 1 Process flow diagram.

Material Processing

HDPE and ceramic material (Al_2O_3 and SiC) have been selected as matrix material and reinforcement respectively. The aim of this study was to investigate the new possibilities of reusing the plastic solid waste (PSW) while reinforcing some of the foreign particles. HDPE is available in various grades as we are working in area of extrusion so extrusion grade HDPE has been selected. Both the materials were blended together, in various proportions by using twin screw extruder (Fig. 2), in weight percentage and tested for their rheological properties (MFI) (as per ASTM-D-1238 standard), which came out to be in range of 12 g/10 min.

Setup of twin screw extruder has been shown in Fig. 2, used for uniform mixing of the matrix material and reinforcements. Rheological properties of HDPE may vary as it is very difficult to know about the number of processes done on available material. Further, thermal behavior of various proportions was tested by using DSC testing equipment. The major reason behind thermal testing is to get information about the melting and decomposition range of the proposed material. After getting results from DSC, proportions were prepared in higher quantities and fed into the twin screw extruder for uniform dispersion of reinforcement and matrix material and obtained in form of pellets. After getting material from the twin screw extruder, pellets were fed into the single screw extruder (L/D ratio-20) and filament wires were obtained according to Taguchi L9 array. Those wires were tested for their mechanical and thermal properties on universal tensile testing machine and DSC, respectively.

Experimentation

Experimentation of HDPE and reinforcement starts with the blending of the materials with the help of the proper bonding agent, i.e., paraffin wax. Three different proportions were prepared in weight percentage. For this study $\text{SiC}/\text{Al}_2\text{O}_3$ of size 20 μm were used in equal weight percentage, i.e., 10%, 20%, and 30%. After preparing three different proportions of base matrix and reinforcements as said above MFI (melt flow index (grams/10 min)) was calculated by using the melt flow indexer machine to understand flow behavior of materials as this material has to be run through the FDM setup. The reason behind testing of rheological and thermal properties is that FDM setup optimizations have to be done on the basis flow behavior and thermal behavior of reinforced material. Table 1 shows the MFI data for the various proportions of HDPE and $\text{SiC}/\text{Al}_2\text{O}_3$ reinforcements.

The MFI is one of the standard tests for ascertaining the rheological properties of polymeric materials. It defines the ease with which a thermoplastic polymer can flow. In the present study MFI investigations have been conducted as per ASTM-D-1238 standard. As observed from Table 1, MFI values for different proportions of reinforcement are coming in range of 10–12 g/10 min, where as MFI value for 100% HDPE is coming around 9–10 g/10 min. Hence it can be said that after adding the reinforcements, MFI of the composite material increases up to some extent. After establishing the MFI of the composite material, further thermal behavior was tested by using differential scanning calorimeter (DSC).

Thermal Testing

The thermal testing of the material comprises of the DSC test, where material can be tested along the line of the melting range, which ensures the proper and accurate measurement of thermal characteristics of the material. Fig. 3 depicts the basic setup of the DSC machine.

Melting range of the material comprises melting temperature, enthalpy, and the decomposition of the material. Various samples of the waste polymer comprising of the HDPE, Al_2O_3 , and SiC were prepared by using the twin screw extruder to ensure

Fig. 2 Twin screw extruder setup.

Table 1 Melt flow index (MFI) values for different proportions by weight percentage

Serial number	High-density polyethylene (HDPE) 100%	HDPE + SiC + Al ₂ O ₃ (by weight)		
		Proportion 1 90% + 5% + 5%	Proportion 2 80% + 10% + 10%	Proportion 3 70% + 15% + 15%
1	8.935	11.19	10.03	9.98
2	10	11.8	10.825	11.185
3	9.94	10.8	11.01	12
Avg	9.625	11.26333	10.62167	11.055

**Fig. 3** Differential scanning calorimeter (DSC) setup.

the high dispersion rate and tested to study the effect of the reinforcement on the thermal properties of the waste polymer. **Fig. 4** shows the DSC graph of 90% HDPE and 10% (Al₂O₃ and SiC).

Fig. 4 shows the DSC graph of the waste polymer consisting of a defined quantity of the reinforcement. Under this, three cycles of testing were performed to eliminate any kind of stress and materials history as this material is a waste polymer that may consist of some prestored history because of the number of recycling cycles done previously. In the first cycle of heating all the stress was assumed to be relieved. Further it can be clearly seen that melting temperature of the proportion varies from 120°C to 122°C, shown in hatched area in graph. Melting of the material starts from 122°C and ends at 132°C. While under melting state, the material's enthalpy was calculated to be -500.51 mJ while enthalpy of the material also follows a particular trend. In the first cycle after melting of the material at 122°C–132°C, a small drop in the graph line occurs, which shows the melting of the material. As primary material, HDPE has been melted previously at 122°C. This sudden drop might be due to the melting of the some pigment (color) present in waste polymer. Al₂O₃ and SiC cannot melt at this temperature as these contain melting range above 1000°C. After the first cycle of heating up to 300°C, the material was given a cooling cycle. It can be seen from **Fig. 4** that when the temperature came close to 119°C a sudden peak appears, which shows the convergence of material from melt stage to solid stage releasing some energy, i.e., 471.85 mJ and continuing to release energy. In the second cycle of heating after melting of material, the curve remains stable unlike in the first heating cycle and continues to follow same trend in the third heating cycles also. Pigment or any impurity is assumed to be eliminated in the first cycle of heating. Another sample of different proportion, i.e., 80% HDPE and 20% reinforcement (Al₂O₃ and SiC), was tested to ensure the trend followed by the previous sample. After DSC, test material was set for further experimentation.

Filament Preparation

After successful testing of the composite material all three proportions (as per **Table 1**) were prepared in higher quantities and subjected to single screw extruder for preparation of filament wire that could possibly run on the FDM machine. **Table 2** shows various parameters selected and their corresponding signal to noise (SN) ratios for selected output parameters according to the Taguchi L9 orthogonal array.

Form SN ratio analysis it has been observed that the second level of composition (80% HDPE + 10% SiC + 10%Al₂O₃), first level of die temperature 110°C, and third level of barrel temperature 130°C give the best result but this combination does not exist

Fig. 4 Differential scanning calorimeter (DSC) graph for the proportion 90% high-density polyethylene (HDPE) and 10% (Al_2O_3 and SiC).

Table 2 Control log for experimental study

S.No	Proportions	DT	BT	PS	SN for PS	PL	SN for PL	B S	SN for BS	%age elongation	SN for % elongation

Note: DT, BT, PS in (MPa), PL in Newton, BS (MPa) signifies Die temperature in °C, barrel temperature in °C, peak strength, peak load and break strength respectively.

in the present analysis. So, a confirmatory experiment was performed and values were counterverified. Finally, peak strength 24.53 MPa, peak load 55.16 MPa, break strength 24.56 MPa, and % elongation 10.01% has been attained.

Proportions, which were prepared according to the [Table 1](#), were processed on single screw extruder for filament preparation (see [Fig. 5](#)). After preparation of filament wires, samples from each wire have been taken to test thermal properties on DSC testing equipment.

After obtaining all the results for the mechanical testing, the wire was made to run on the fused deposition modeling machine (3D printer). Further, parts with definite dimension (20 mm × 20 mm × 20 mm) were made by the same route and prepared for the investment casting. [Fig. 6](#) shows the actual photographs of HDPE parts prepared by the 3D printer. The motive of the investment casting of the parts is to enhance the surface properties of the metal or material that is being used for casting. In this process, after dewaxing, reinforcement would remain inside and would adhere to the metal surface being casted. This process would make final casted product a functionally graded material, carrying reinforcements on its surface enhancing surface properties.

After making all the 3D parts with the help of FDM machine, parts were taken for the investment casting as per steps recommended ([Singh, 2013](#)). For investment casting, aluminum has been chosen being a soft metal as compared to the other metal so that effects could be seen clearly. For investment casting purpose an IC tree was designed first as given in [Fig. 7](#). Different parts of the IC tree have been labeled.

After preparing the IC tree all the parts prepared on 3D printing machine have been attached to the arms of the tree, and the process for the IC has been followed.

At first stage of experimentation, pilot experiments were conducted wherein cubical patterns were prepared. It has been found that size of FDM reinforced pattern expands while layered on the platform and expansion of patterns lies between 0.13 and 0.67 mm.

Fig. 5 Filament wire prepared by single screw extruder.

Fig. 6 Parts prepared by fused deposition modeling (FDM) machine by using filament wire.

Barrel finishing, one of the widely used processes for surface finishing of FDM parts, was introduced at the intermediate stage for the improvement of surface finishing of FDM reinforced patterns prior to ceramic molding. Ceramic molding was done using zircon sand and ceramic molds were prepared. Finally, the prepared IC molds and the pouring of molten Al metal into cavity are shown in **Fig. 8(a)** and **(b)**, respectively.

Fig. 8(a) and **(b)** shows the various stages completed during the investment casting. After completion, the IC parts were then segregated and collected. Further collected parts were then finished by disk polishing machine in order to clean the surface and then optical micrographs were taken to ensure the presence of the SiC and Al_2O_3 on the surface of the casted product. **Fig. 9** shows the optical micrographs of the final parts showing reinforcements of the surface.

In **Fig. 9**, the presence of the reinforced particles (SiC, Al_2O_3) can be clearly seen. Further to ensure the presence of the reinforcements, part was subjected to the scanning electron microscope and the image was taken as shown in **Fig. 10**.

In **Fig. 10**, the presence of the reinforced particle can be clearly seen on the surface of the casted product. Further it would lead to the enhancement of the surface properties of the final product. In this article focus was to develop the functionally graded material in the form of metal matrix composite leading to the increase in the application domain of the material prepared.

Conclusions

In the present case study, aluminum matrix composite (AMC) has been successfully developed using new methodology. Initially, in-house prepared filament wire was tested for the mechanical properties and very promising results (peak strength 24.53 MPa, peak load 55.16 MPa, break strength 24.56 MPa, and % elongation 10.01%) have been attained. After filament wire testing, wire was used to prepare patterns on then FDM machine. Patterns were then used for sacrificial investment casting and AMC was

obtained. AMC was subjected to microstructure evaluation, which highlighted the presence of SiC and Al_2O_3 particles. Further in this article various other processing techniques have been discussed that are necessary for taking out the vital results in terms of the surface properties. After casting of the product, SEM analysis was carried out, which shows the uniform presence of SiC and Al_2O_3 particles on the surface to ensure the formation of the functionally graded material.

Introduction

The rapid development of plastic/polymer consumption in different applications led to the research of innovative recycling procedures and improvement in previous strategies (Al-Salem *et al.*, 2009). Plastic/polymer solid waste (PSW) is showing new challenges and opportunity to the universe regardless of its technological advances and sustainability awareness (Al-Salem *et al.*, 2009). Most common waste plastic accumulation is in municipal solid waste (MSW). Plastics in MSW consist of different kind of polymer wastes like high density polyethylene (HDPE), polyethylene terephthalate (PET), plastic films made of low density polyethylene (LDPE), and of hard plastic made of HDPE (Rigamonti *et al.*, 2014). After a single use, most of the plastic/polymer is disposed resulting in huge amount of waste collection (Jayaraman and Halliwell, 2009). The level of plastic waste in landfills is increasing, taking up a larger and larger space, and taking hundreds of years for disposal (AnuarSharuddin *et al.*, 2016). That is why recycling of PSW becomes a present-day need. Polymer recycling is a method for reduction of environmental problems caused by polymeric waste generation from day-to-day applications of polymer materials such as packaging and construction (Hamad *et al.*, 2013). Reusing plastics has a number of advantages, characterized by (1) conservation of fossil fuels since plastic production uses 4%–8% of global oil production, i.e., 4% as feedstock and 4% during conversion (Perdon, 2004; JCR, 2006); (2) reduction of energy and MSW; and (3) reduction of carbon dioxide (CO₂), nitrogen oxides (NO_x), and sulfur dioxide (SO₂) emissions. The continued development of recycling and recovery technologies, investment in infrastructure, the establishment of viable markets, and participation by industry, government, and consumers are all considered priorities of the highest order (Scheirs, 1998). Various recycling methods are available in the present-day scenario; some of them are primary, secondary, tertiary, and quaternary. Further they can be subdivided in to various techniques like mechanical, chemical, incineration, etc. (Kumar *et al.*, 2011). Amongst these techniques and methods, mechanical methods are more popular and simple including extrusion, pelletizing, drawing, etc. (Campbell and Spalding, 2013). In life cycle assessment (LCA) studies, a “system” is defined (with boundaries indicated by broken lines). Energy and raw materials from the “environment” are used in the system. Emissions, including solid waste, leave the system and enter the environment. Waste prevention includes the role of cleaner production, innovative services, sustainable consumption, and prevention by design (Kirkby *et al.*, 2004). Fig. 1 shows roles of waste prevention and integrated waste management. The low cost and remarkable properties like strength, temperature/chemically resistance, nonconductivity, and reprocessability or reusability (Rosato *et al.*, 2001) of polymers attract the interest of researchers for their use in various applications in the field of engineering, aerospace, biomedical science, etc. Thermoplastics materials have low melting point and could be easily molded into a variety of shapes by heating (Bodener and Micklos, 2004). The biocompatibility of some polymers makes them possible for use in biomedical applications. The polymers like PVC, PP, polyether ether ketone (PEEK), poly lactic acid (PLA), etc. are the most widely used polymers in the biomedical field, particularly in the fields of tissue engineering and drug delivery.

Biocompatibility is defined as adaptability of some foreign component by the body environment without producing any adverse effect to the functionality of the system. In medical science, biocompatibility is known as the interaction of any medical part or component material with the tissue or living system. So in general a biocompatible object does not provide any harm to the patient (Lendlein and Sisson, 2011; Tian *et al.*, 2012). Most plastics intended for medical devices including medical grades of PVC, polyethylene, polycarbonate, PEEK, Ultem PEI, polypropylene, polysulfone and polyurethane, and all these have to undergo the stringent tests before their actual use in medical applications (Majumdar, 1998). As compared to other materials the mechanical processing of the polymers requires much less energy (Rosato *et al.*, 2001; Abeykoon *et al.*, 2014). The extrusion process is mainly used for conversion of raw polymer grains into usable rod or wire form. For reinforcement of ceramic or metal particles in the polymer matrix, a twin-screw extruder has been generally used (Erdmenger, 1964). Twin-screw extruders have numerous advantages over single-screw extruders like better feeding and more positive conveying characteristics, i.e., allow the machine to process hard-to-feed materials (Wendaal, 2014). Some studies highlighted that the synthetic HAp particles were reinforced into a polymer matrix to produce composites for medical applications and corotating twin-screw compounding produces an effective and homogeneous distribution of HAp particles in a polymers matrix, which is maintained after compression molding (Wright, 2016; Wang *et al.*, 1994).

These polymer filaments can be easily used in the biomedical applications with the help of additive manufacturing (AM). The traditional way of implant fabrication has been now replaced with AM, in which the implants have been directly fabricated from the 3D CAD data (Kurtzman, 2010). Nowadays the AM and CAD have been directly integrated with the 3D imaging techniques, i.e., MRI, CT scan, etc. (Tukuru *et al.*, 2008). In AM, functional and nonfunctional prototypes of the polymers have been fabricated by continuously adding layer by layer of material until the digital CAD model has been completely converted into a real-time 3D object (Huang *et al.*, 2015). During the past decade a number of patents have been claimed by inventing vivid types of AM

Fig. 1 Respective roles of waste prevention and integrated waste management. Powers, R.W., 1995. The role of recycling in municipal solid waste management to the year 2000. *Japan Tappi Journal* 49(3), 513–519.

technologies, thus resulting in more and more users being able to install 3D printers to produce functional products (Wohlers and Caffrey, 2013; Korpela *et al.*, 2013; Zein *et al.*, 2002). The scope of AM is continuously increasing for biomedical applications with the combination of natural and synthetic polymers by reinforcement of ceramics, metals, and other foreign particles in these polymers (Seitz *et al.*, 2005).

FDM is one of the most widely used AM techniques for fabrication of 3D scaffolds having adequate mechanical, thermal, as well as surface properties for proper implant placement (Galantucci *et al.*, 2009; Sood *et al.*, 2009). FDM produces the best fit bio-functional parts in very short duration without waste material. FDM uses the 3D CAD model to fabricate the actual product. Initially the CAD created file has been converted into STL format, i.e., machine language, by using a preprocessing software (Boschetto *et al.*, 2013; Singh *et al.*, 2016, 2017). The .stl file has been further sliced into two dimensional layers by using an open source software K-Slicer (Chua *et al.*, 2010). The filament has been extruded through the extrusion head having temperature near about the melting point of the material. The temperature of the chamber remains constant to prevent the solidifying material from experiencing thermal stress and distortion. The main advantages of FDM over other AM techniques are its trouble-free handling, and it provides controllable factors that have been adjusted according to the required properties of the fabricated part (Sahebrao *et al.*, 2009; Ivanova *et al.*, 2013). The controllable parameters of FDM affect the various properties of the extruded products (Singh *et al.*, 2016).

In this work the detailed procedure has been highlighted for development of RT by preparing feed stock filament wire from recycled/waste HDPE and LDPE polymers as base matrix with different particle sizes of SiC/Al₂O₃ as reinforcement. The HDPE and LDPE were collected from household waste and after manual segregation, different particle size (i.e., single particle size (SPS), double particle size (DPS), and triple particle size (TPS) in different proportions) of SiC/Al₂O₃ were added independently to HDPE and LDPE. The melt flow index (MFI) of these combinations/proportions was computed as per ASTM D1238-73 standard. After evaluation of MFIs, the best combinations were selected and used for filament wire preparation on the twin-screw extruder. The output properties, i.e., peak strength, break strength, peak elongation, break elongation, etc., were modeled for multifactor optimization. The filament wires were made to run on commercial fused deposition modeling (FDM) three dimensional printer (open source) for preparation of cylindrical pins (selected as RT) for wear testing. These pins were made to run on pin on disk apparatus for ascertaining the wear properties. Finally differential scanning calorimetry (DSC) was also performed to predict thermal behavior for field engineers.

Methodology

Melt Flow Index Tester

As stated, HDPE and LDPE have been selected as parent material for this study. The reason behind the selection of HDPE and LDPE was that some of the researchers have gotten good results after making reinforcements of different materials like talc powder, waste printed circuit boards, recycled wood, sand, natural fiber in HDPE and LDPE (Sanchez-Soto *et al.*, 2008; Yang *et al.*, 2015). In this work metallic powder like SiC, Al₂O₃ have been selected as reinforcement to improve the mechanical properties. After selection of reinforcements a pilot experiment was performed for establishment of MFI for various combinations of proportions of SiC, Al₂O₃ with HDPE and LDPE matrix on melt flow indexer machine (see Appendix A). MFI is the standard test for obtaining

flow behavior of polymer (Navratil *et al.*, 2015). MFI of ABS is 2.411 g/10 min as per ASTM-D-1238 standard (at 230°C temperature and 3.8 kg force) (Singh and Singh, 2015). MFI of HDPE and LDPE was established by varying various combinations/proportion of HDPE and SiC, Al_2O_3 .

Procedure to determine MFI:

- To determine MFI of certain composition, mixture is poured into the cylinder and a temperature condition is set.
- Then the machine is left for some time to achieve the predefined temperature.
- After establishing a predefined temperature, pressure is applied with the piston bar into the cylinder by certain weight above the piston bar.
- With application of pressure with certain weight, flow of material occurs through the die face in the form of wire.

The material collected in 10 min is further subjected to weighing balance to determine its mass. So, deposition of material through the melt flow tester in 10 min is considered as the MFI. Fig. 2 shows the basic schematic and pictorial view of MFI tester.

From Appendix A, various composition sets for SPS, DPS, TPS particles of SiC/ Al_2O_3 were considered and least values for each set are shortlisted in Appendix B.

Twin-Screw Extruder

The twin-screw extruder was developed more than 20 years ago, for continuous production of highly uniform and finely structure products. It is widely used to produce biosourced plastics, cellulose pulps, and food products. Figs. 3 and 4 show the schematic and pictorial view of a twin-screw extruder. For this study commercial make HAAKE Mini CTW, Germany has been used.

As per Appendix B, various combinations of HDPE/LDPE and SiC/ Al_2O_3 were selected and used for filament wire preparation on twin-screw extruder. Fig. 5 shows the wires of HDPE and LDPE prepared on twin-screw extruder. Four process parameters were taken for twin-screw extruder (namely, composition, load, rpm, and temperature of barrel). Six levels of one parameter (composition/proportion) and three levels of the other three parameters (load, rpm, and temperature of barrel) were taken and explored by using Taguchi L18 orthogonal array technique separately for HDPE and LDPE. Appendix C shows various combinations of input parameters taken for this study.

Universal Tensile Tester

Tensile test is the most accepted test regarding judgment for quality of weld. This test is performed on a universal tensile tester to check the tensile strength at peak as well at break of joint. Fig. 6 shows the universal tensile tester having capacity of 5000 N, used only for the plastic or rubber material. Plastic wires, plastic flats, or strips of any size can be measured by this universal tensile tester.

The filament wires so produced as per Appendix C were tested mechanically on a universal tensile tester (UTT). The results of UTT are summarized in Appendix D. Fig. 7 shows peak load versus elongation curve of HDPE reinforced filament.

Fused Deposition Modeling

In 1988, FDM was invented in the United States and was patented in 1992 as a rapid prototyping/AM technology. Commercially the FDM is marketed by the Stratasys Inc. Nowadays, FDM is a well-known additive technology used for the fabrication of actual or nonactual prototypes. Similar to other AM technology, it is also a manufacturing tool that produces the part by stacking the material in a layer-by-layer technique. It is commonly used for pattern making, modeling, and various production applications. Fig. 8 shows the complete view of the FDM process.

Various advantages and disadvantages of FDM process are listed as in Table 1.

Fig. 2 MFI Testing.

Fig. 3 Schematic of twin-screw extruder.

Fig. 4 Pictorial view of twin extruder (make: HAAKE Mini CTW, Germany). Wire of HDPE, Wire of LDPE.

Fig. 5 Wires of HDPE and LDPE made using twin-screw extruder.

Cylindrical pins of Pure HDPE (100% by weight), pure LDPE (100% by weight), TPS reinforced HDPE (i.e., HDPE as 60% by weight), Al_2O_3 -300G as 13.33% by weight, Al_2O_3 -400G as 13.33% by weight, Al_2O_3 -500G as 13.33% by weight, and TPS reinforced LDPE (i.e., 60% by weight), SiC-300G as 13.33% by weight, SiC-400G as 13.33% by weight, SiC-500G as 13.33% by weight as shown in Fig. 9 were prepared on commercial FDM setup without change in any hardware or software of the system.

Fig. 6 Universal tensile tester in manufacturing Research Lab (GNDEC, Ludhiana).

Fig. 7 Peak load versus elongation curve for HDPE.

Pin on disk experimentation

The pin on disk wear test was performed as per the ASTM G99 standard under dry sliding conditions at room temperature with a sliding velocity of 0.63 m/s and 80 mm track diameter. The machine was equipped with a data acquisition system.

The counter sliding surface for the pin was prepared by pasting silicon carbide (SiC) paper (600 grit size) on a steel disk (EN-32; hardness 65 HRC). **Fig. 10** shows a schematic of the pin-on-disk process.

The three process parameters i.e., RPM, load, and time, were taken for pin on disk standard experiment. Appendix E and F show wear values (in μm) for pure HDPE, TPS SiC HDPE, TPS Al_2O_3 HDPE and pure LDPE, TPS SiC LDPE, TPS Al_2O_3 LDPE pins under different conditions as per L9 orthogonal array technique.

Based upon Appendix E, it can be summarized that the Al_2O_3 based TPS reinforcement pin exhibits lesser wear values than that of pure HDPE and HDPE TPS SiC pins for the same trial runs ensuring better wear properties of the HDPE TPS Al_2O_3 pin.

Similarly, based upon Appendix F, it can be summarized that the SiC based TPS reinforcement pin exhibits lesser wear values than that of the pure LDPE and LDPE TPS Al_2O_3 pins for the same levels ensuring better wear properties of the LDPE TPS SiC pin.

Scanning electron microscopy

Scanning electron microscopy (SEM) has been performed on all HDPE based pins, i.e., pure HDPE, HDPE SiC pin, and HDPE TPS Al_2O_3 pin. **Fig. 11** shows SEM images of the pins at X400 magnification.

Since HDPE has high crystalline and low amorphous regions (more than 90% crystalline), it contains several side chains per 200 carbon atoms in the main carbon skeleton leading to long linear chains. As a result, it is closely packed and highly crystalline in nature. Further, density of HDPE is high and can range from 0.95 to 0.97 g/cm^3 . Although, HDPE with SiC as reinforcement should yield better wear properties than that of Al_2O_3 , as SiC is a harder material than Al_2O_3 , in this case, Al_2O_3 is proving to give better wear results when reinforced with HDPE. This may be due to the fact that the density of Al_2O_3 is more than that of SiC (3.98 g/cm^3 as compared to 3.21 g/cm^3), which means that there will be more particles of Al_2O_3 per unit volume in the HDPE matrix causing more ploughing of reinforcement particles from HDPE matrix when rubbed against the disk (during the pin on disk experiment), thus ensuring better wear properties. Similarly, SEM has been done for pure LDPE, LDPE SiC pin, and LDPE TPS Al_2O_3 pin. **Fig. 12** shows SEM images of the pins at X400 magnification.

As observed from **Fig. 12**, voids were created due to dislocation of reinforcement particles from LDPE matrix when rubbed against the disk during the pin on disk experiment. It can be clearly seen that small dislocations have been created in the case of the SiC reinforced pin as opposed to that of Al_2O_3 . Since LDPE has low crystalline and high amorphous regions and it contains fewer side chains per 100 carbon atoms in the main carbon skeleton, as a result, it is not very closely packed and less crystalline in nature.

Fig. 8 Fused deposition modeling (FDM) process. Source: www.custompart.net.

Table 1 Advantages and disadvantages of FDM process

Advantages of FDM process	Disadvantages of FDM process
● Fabrication of functional prototypes/parts ● Availability of raw material ● Wastage of material is minimum ● No need of any toxic solvent ● Very low tolerance ● Ease in material change ● Support removal is easy	● Swelling of material in case of high temperature ● Surface finishing is not up to the mark ● Formation of gap in between the layers reduces the part strength ● Choking of nozzle head ● Slow manufacturing process ● Unpredictable distortion and shrinkage

Fig. 9 From left to right: Pins of pure HDPE, TPS SiC HDPE, TPS Al₂O₃ HDPE, pure LDPE, TPS SiC LDPE, TPS Al₂O₃ LDPE.

Further, density of LDPE is in range from 0.91 to 0.94 g/cm³. SiC, being a harder material than Al₂O₃, gave better wear results, when reinforced with LDPE as lesser ploughing of reinforcement particles from LDPE matrix will be there when rubbed against the disk, thus ensuring better wear properties.

Differential scanning calorimetry

Thermal behavior of the material is one of the major constraints for the use of developed filament in clinical dentistry. For thermal testing of the material in the present study DSC has been used. The term DSC simply implies that during a linear temperature ramp, quantitative calorimetric information can be obtained on the sample. This constantly rising temperature ensures the proper and accurate measurement of thermal characteristics of the material. The material exhibits heat flow as a function of temperature and time. DSC comprises of glass transition, melting point, enthalpy change, and decomposition of the material with respect to the rising of temperature. Common usage includes investigation, selection, comparison, and end-use performance evaluation of materials in research, quality control and production applications. For thermal analysis METTLER TOLEDO, Model DSC3, Swiss make with STAR[®] (SW 14.00) software was used in N₂ gas environment. The typical DSC setup determines the behavior of applied samples by taking references from a standard sample, both enclosed in a metallic crucible (Al or platinum). Further, thermal analysis of above stated TPS sample at level 3 for composition (major contributing factor, i.e., HDPE as 60% by weight, Al₂O₃-300G as 13.33% by weight, Al₂O₃-400G as 13.33% by weight, Al₂O₃-500G as 13.33% by weight), level 2 for temperature

Fig. 10 Schematic of the pin-on-disk process. Reproduced from Kennedy, F.E., Lu, Y., Baker, I., 2015. Contact temperatures and their influence on wear during pin-on-disk tribotesting. *Tribology International* 82, 534–542.

Fig. 11 SEM images of different HDPE pins. SEM for pure HDPE pin, SEM for TPS HDPE SiC pin, SEM for TPS HDPE Al₂O₃ pin.

Fig. 12 shows SEM images of different LDPE pins. SEM for pure LDPE pin, SEM for TPS LDPE SiC pin, SEM for TPS LDPE Al₂O₃ pin.

(190°C), level 2 for RPM (40 rpm), and level 1 for load (5 kgf) was performed by using commercial DSC setup (Make: Mettler Toledo-DSC). The thermal plot for this sample is shown in **Fig. 13**.

Fig. 13 clearly depicts the 03 number of cycles for testing on DSC setup. These repetitions were necessary to eliminate any sort of effect arisen due to contamination and prestored history. The first cycle has probably removed the above said effect. Further melting range of the material can be clearly seen in the graph in the hatched area i.e., 175°C to 180°C. Melting of material starts at 175°C and goes to 180°C. Enthalpy in that melting range was counted to be – 229.65 mJ with a trend. In the first cycle of the DSC testing a heaped hatched curve was seen after the melting of HDPE. This shows the decomposition of some substance but surely this is not HDPE, as HDPE decomposes above 300°C. So, this might be decomposition of some of the contamination present in the form of the pigment (color). After that, the cooling cycle starts and sudden cooling can be seen as a straight vertical line. It can be easily observed that there is no evidence of decomposition of HDPE. Some uniformity has been observed in the 2nd and 3rd cycle also without any evidence of HDPE decomposition. After 3 cycles of heating, no significant effect was observed in terms of

Fig. 13 DSC results of TPS Al₂O₃ reinforced HDPE sample.

melting and decomposition of material thus it can be ascertained that the part prepared from such filament wire will have high thermal stability. The results are in line with the observations made by other investigators.

Similarly, thermal analysis of above stated TPS SiC based LDPE sample (LDPE as 60% by weight, SiC-300G as 13.33% by weight, SiC-400G as 13.33% by weight, SiC-500G as 13.33% by weight) at level 1 for RPM (250 rpm) (major contributing factor), level 2 for time (10 min) and level 2 for load (2 kgf) was performed by using commercial DSC setup (Make: Mettler Toledo- DSC). The thermal plot for this sample is shown in Fig. 14.

Fig. 14 clearly depicts the 03 number of cycles for testing on DSC setup. These repetitions were necessary to eliminate any sort of effect arisen due to contamination and prestored history. First cycled has probably removed the above said effect. Further melting range of the material can be clearly seen in graph in the hatched area i.e., 125°C to 129°C. Melting of material starts at 125°C and goes to 129°C. Enthalpy in that melting range was counted to be - 94.34 mJ with a trend. In the first cycle of the DSC testing a heaped hatched curve was seen after the melting of LDPE. This shows the decomposition of some substance but surely this is not LDPE, as LDPE decomposes above 300°C. So, this might be decomposition of some of the contamination present in the form of the pigment (color). After that, cooling cycle starts and sudden cooling can be seen as a straight vertical line. It can be easily observed that there is no evidence of decomposition of LDPE. Some uniformity has been observed in the 2nd and 3rd cycle also without any evidence of LDPE decomposition. After 3 cycles of heating, no significant effect was observed in terms of melting and decomposition of material thus it can be ascertained that the part prepared from such filament wire will have high thermal stability. The results are in line with the observations made by other investigators.

Results and Discussion

Various signal to noise (SN) ratios of mechanical properties (by considering larger the better type case, independently for each property) as obtained by analysis of variance (ANOVA) by using Minitab software are summarized in Appendix G. Based upon Appendix G, Appendix H shows the percentage contribution of different input parameters on mechanical properties independently (by considering maximum the better type case). The results are at 95% confidence level. As observed from Appendix H, for HDPE, composition is the major factor contributing to peak load, break load, and Young's modulus and temperature is the major factor contributing to peak elongation and break elongation. Similarly, for LDPE, it can be seen that composition is the major factor contributing to peak load, break load, and Young's modulus and load is the major the factor contributing to peak elongation and break elongation. Based upon SN ratios analysis (for combined factor optimization), the overall effect of all the process parameters on mechanical properties is shown as in Table 2.

Fig. 14 DSC results of TPS SiC reinforced LDPE sample.

For HDPE:

From Table 2, it can be observed that level 3 for composition (major contributing factor i.e., HDPE as 60% by weight, Al_2O_3 -300G as 13.33% by weight, Al_2O_3 -400G as 13.33% by weight, Al_2O_3 -500G as 13.33% by weight), level 2 for temperature (190°C), level 2 for RPM (40 rpm) and level 1 for load (5 kgf) are the optimized conditions. Hence, it can be concluded that aluminum oxide (Al_2O_3) based TPS reinforcement will exhibit better mechanical properties of the feed stock filament.

For LDPE:

From Table 2, it can be observed that level 6 of composition (i.e., LDPE as 60% by weight, SiC-300G as 13.33% by weight, SiC-400G as 13.33% by weight, SiC-500G as 13.33% by weight), level 2 for temperature (160°C), level 2 for load (10 kgf), level 2 for RPM (40 rpm) are the optimized conditions. Hence, it can be concluded that silicon carbide (SiC) based TPS reinforcement will exhibit better mechanical properties of the feed stock filament.

Various SN ratios of wear as obtained using L9 technique for Al_2O_3 based TPS reinforced HDPE pin and SiC based TPS reinforced LDPE pin are summarized as in Table 3.

Also, percentage contributions of each process parameter on wear properties are summarized in Table 4.

From Table 4, it can be analyzed that for wear of HDPE, load is the major process parameter with 56.49% contribution effecting wear values followed by RPM with 20.42% contribution and time with 13.94% contribution.

Similarly for wear of LDPE, RPM is the major process parameter with 37.57% contribution effecting wear values followed by time with 32.46% contribution and load with 20.17% contribution. After analyzing all SN ratios, the combined effect of all the process parameters on wear properties is shown as in Fig. 15.

The effect of all the process parameters and their ranking for wear of TPS reinforced Al_2O_3 -HDPE pin TPS reinforced SiC-LDPE pin is shown as in Table 5.

Based upon Table 5, it can be summarized that Al_2O_3 based TPS reinforced HDPE pin will exhibit better wear properties at level 3 of load (i.e., 3 kgf load as major factor) followed by level 3 of rpm (500 rpm) and level 1 of time (5 min).

Similarly, from Table 5, it can be summarized that SiC based TPS reinforced LDPE pin will exhibit better wear properties at level 1 of RPM (250) followed by level 2 for time (10 min) and level 2 for load (2 kgf).

The wear tracks for HDPE pins (pure and Al_2O_3 based TPS reinforced HDPE) are shown in Fig. 16, which clearly highlights the extent of wear on pins, when rubbed against the disk. It has been observed that the wear track for the pure HDPE pin is quite sharper than that of tracks for the TPS based HDPE pins.

Conclusion

The results of study highlights that Al_2O_3 based TPS reinforcement in HDPE matrix and SiC based TPS reinforcement in LDPE matrix resulted in better wear properties under similar service/processing conditions. (See Appendix E at experiment no. 6, wear of pure HDPE was 1244 μm , which was improved as 1120 μm in case of HDPE-TPS-SiC and 1020 μm in case of HDPE-TPS- Al_2O_3). In case of LDPE, (Appendix F) for experiment no. 3, wear of pure LDPE was 1976 μm , which was improved as 1357 μm in case of LDPE-TPS-SiC and 1545 μm in case of LDPE-TPS- Al_2O_3 . Further, results of DSC concluded that the RT prepared from such filament wire will have high thermal stability as there is no evidence of decomposition found after 3 cycles of heating and cooling. Hence the proposed proportion/composition of Al_2O_3 based TPS reinforcement in HDPE (up to 175°C) and SiC based TPS reinforcement in LDPE matrix (up to 125°C) is highly suitable for RT applications.

Note: G represents grade of abrasives. It should be noted that the SPS represents single particle size (of either 300, 400, 500 American foundry society (AFS) grade), DPS represents two particle sizes in equal proportion by weight (of combination of either of two from 300, 400, 500 AFS grade), and TPS represents three particle sizes in equal proportion by weight (of 300, 400, and 500 AFS grade). It has been observed that in the reported literature, researchers have studied only the effect of SPS and much less exploration is done in the field of study of MFIs considering DPS and TPS. The above stated sizes of SiC/Al₂O₃ are taken, considering the commercial availability of these.

Large Biomass Burners for Fuel Switch in Existing Fossil Fuel Based Plants

Dalibor Petković, University of Niš, Pedagogical Faculty in Vranje, Partizanska, Vranje, Serbia

Introduction

Energy is one of the most fundamental parts for any country and it is known as a strategic commodity. Any uncertainty about its supply can threaten the functioning of the economy, particularly in developing economies.

Energy services could be greatly improved by using agricultural biomass in small-scale combustion units. Wood pellets are a reliable and proven fuel to be used in small-scale combustion units. However, these units should preferably be able to use different types of biomass depending what it is locally available. Therefore, studies have been focused on exploring the suitability of using agricultural residues for small-scale heat and power generation using direct combustion. Steam-treated pellets can help to address technical barriers that limit the uptake of pellets as a fuel for electricity generation, but there is limited understanding of the cost and environmental impacts of their production and use.

A modified Hartmann dust explosion tube was employed to determine the Minimum Explosible Concentration (MEC) and the flame speed for three Pakistani agricultural wastes: bagasse, rice husk and wheat straw (Saeed *et al.*, 2015) where it was shown the lean limits for these pulverized agricultural waste biomasses were comparable to that of pulverized wood but were much leaner than those for coal and hydrocarbon fuels, which indicate that these biomasses are highly reactive. In study (Cardozo *et al.*, 2014) was compared the combustion of different agricultural residues in a single unit designed for wood pellets. In study (McKechnie *et al.*, 2016) was investigated life cycle environmental (greenhouse gas (GHG) and air pollutant emissions) and financial implications of electricity generation from steam-treated pellets, including fuel cycle activities (biomass supply, pellet production, and combustion) and retrofit infrastructure to enable 100% pellet firing at a generating station that previously used coal. Impacts of retrofit infrastructure become increasingly significant at lower generating station capacity factors, further favoring steam-treated pellets for both environmental and financial metrics (McKechnie *et al.*, 2016). In study (Nilsson *et al.*, 2011), the costs and energy requirements for the production of pellets from agricultural raw materials were analyzed. The energy use in manufacturing pellets from air-dried crops was generally no higher than when moist sawdust was used as the raw material. The objective of work (Carvalho *et al.*, 2013) was to evaluate the technical and environmental performance of a 15 kW pellet boiler when operated with different pelletized biomass fuels, namely straw (*Triticum aestivum*), Miscanthus (*Miscanthus _ giganteus*), maize (*Zea mays*), wheat bran, vineyard pruning (from *Vitis vinifera*), hay, Sorghum (*Sorghum bicolor*) and wood (from *Picea abies*) with 5% rye flour. The investigation in the international market shows that mixed biomass pellets are promising fuels and with the appropriate support these fuels have many prospects for the future (Karkania *et al.*, 2012). The use of biomass pellets would not only create new market opportunities for agricultural industries, it would also reduce dependence on coal, as well as the greenhouse gas emissions associated with coal use (Karkania *et al.*, 2012). In paper (Tauro *et al.*, 2018) was examined the potential for biomass pellets to become a sizable low-carbon, renewable energy source that could compete with and substitute fossil fuels in specific economic sectors in Mexico where it was estimated that the market energy potential for pellets from currently available agricultural and forest residues in Mexico is between 131 and 233 PJ/yr, with total costs ranging from 6.3 to 12.8 USD/GJ. In paper (Dai *et al.*, 2015), a ceramic foam burner with embedded alumina pellets was designed, which set different shapes of tubes by taking can advantage of the discrete pellets. An experimental system was built to study the effects of the pellet diameter and pellet location on the combustion of low-concentration coal mine methane (LCM) (Dai *et al.*, 2015). Results indicates that the heat transfer features of 13-mm pellets are more similar to those of 10-PPI ceramic foam compared with 6-mm pellets and 9-mm pellets (Dai *et al.*, 2015). The combustion performance in a double-layer burner packed with alumina pellets of different diameters was experimentally studied in article (Gao *et al.*, 2012). In study (Qu and Feng, 2015), methane/air combustion in a two-zone catalytic alumina pileup-pellets burner with equivalence ratios varying from 0.55 to 0.70 was researched. Torrefied biomass has several benefits, such as higher energy density, good grindability, higher flowability and uniformity (Li *et al.*, 2012). The outlet of a mechanical biological treatment plant for mixed municipal solid waste is further processed to produce RRBf (Refined Renewable Biomass Fuel) within the frame of the EU LifeP project MARSS (Material Advanced Recovery Sustainable Systems) (Schulzke *et al.*, 2017). In paper (Dasappa *et al.*, 2004) addresses case studies of a low temperature and a high temperature industrial heat requirement being met using biomass gasification (Dasappa *et al.*, 2004). In paper (Verma *et al.*, 2017) provides a detail review on the need of drying of biomass before co-firing, different technologies used for biomass drying, biomass co-firing to the existing coal fired power plants and the environmental benefits of biomass co-firing.

In this study is presented burners are based on innovative variant of reciprocating grate. Water cooled double wall construction reducing the overall price of construction. There is high variability of potential fuels to be used (e.g. communal waste, all types of biomass (pellets (wood and agricultural), biomass residues, wood chips, wood debris, coal etc.).

Fig. 1 The biomass treatment process flowchart.

Materials and Methods

Biomass Waste Management

According to the European Union standardization there are six procedures in the biomass waste treatment process:

1. Eco-design,
2. Biomass waste decreasing,
3. Biomass waste reusing,
4. Recycling and making compost,
5. Energy from biomass waste,
6. Biomass waste disposing.

In order to optimize the system for biomass waste management based on decreasing of pollution of life environment and for the cheapest solution there is goal to develop the biomass waste management process. This innovative solution could lead to revolution in the biomass waste issue. By entering of the main data for biomass waste, quantity and composition for the some region, the client could know which is the best solution for the biomass waste treatment and transport for the region. Several biomass waste treatments are included:

- Recycling,
- Combusting,
- Making compost,
- Performing anaerobic digestion, and
- Disposing of biomass waste.

There are several indicators which are calculated according the input data. These indicators are:

- Global warming,
- Heavy metals emission,
- Nitrogen oxide emission,
- Smog formation,
- Water pollution.

Therefore the system has seven modules. These modules

- Calculation of emissions from collection and transport of biomass waste,
- Calculation of emissions from anaerobic digestion,
- Calculation of emissions from combustion,
- Calculation of emissions from recycled waste,
- Calculation of emissions from disposal,
- Calculation of emissions from compost,
- Calculation of cost benefit.

Fig. 2 Process flowchart of the combustion plant with biomass.

Fig. 3 Large biomass burner for fuel switch.

Burner for Agricultural Pellets

Fig. 1 shows the flowchart of the biomass treatment process where it was shown the main process steps. Afterwards process flowchart of combustion plant with biomass is shown in **Fig. 2**.

Burners are based on innovative variant of reciprocating grate. Water cooled double wall construction reducing the overall price of construction. High variability of potential fuels to be used in the burners e.g., communal waste, all types of biomass (pellets (wood and agricultural), biomass residues, wood chips, wood debris, coal etc. The burners have high automation (control of speed of grate, control of emission, temperature, pressure in burner). Burner of 4.5 MW have been produced (assembled) and the models are shown in **Fig. 3**. Additionally, whole boilers can be constructed.

Conclusion

The demand for biofuel has increased considerably in recent years, causing shortage of the traditional raw materials sawdust and wood shavings. Use of biomass fuels for electricity generation can simultaneously contribute to a number of common policy objectives, including: increasing the use of renewable energy; reducing greenhouse gas emissions; compliance with air pollutant emissions regulations; and encouraging economic development in communities dependent on agriculture and forestry sectors.

In this article large biomass burners for fuel switch in existing fossil fuel based plants was used for combustion. The burners have high automation (control of speed of grate, control of emission, temperature, pressure in burner). Burner of 4,5 MW have been produced (assembled).

Small-scale wood combustion systems have been well developed and reached a high quality and performance level. The energy efficiency has increased, the emissions have decreased, fully automatic operation systems have been developed and the combustion technology has been optimized for woody biomass fuels.

Introduction

Energy is one of the most fundamental parts for any country and it is known as a strategic commodity. Any uncertainty about its supply can threaten the functioning of the economy, particularly in developing economies.

Energy services could be greatly improved by using agricultural biomass in small-scale combustion units. Wood pellets are a reliable and proven fuel to be used in small-scale combustion units. However, these units should preferably be able to use different types of biomass depending what it is locally available. Therefore, studies have been focused on exploring the suitability of using agricultural residues for small-scale heat and power generation using direct combustion. Steam-treated pellets can help to address technical barriers that limit the uptake of pellets as a fuel for electricity generation, but there is limited understanding of the cost and environmental impacts of their production and use.

A modified Hartmann dust explosion tube was employed to determine the Minimum Explosible Concentration (MEC) and the flame speed for three Pakistani agricultural wastes: bagasse, rice husk and wheat straw (Saeed *et al.*, 2015) where it was shown the lean limits for these pulverized agricultural waste biomasses were comparable to that of pulverized wood but were much leaner than those for coal and hydrocarbon fuels, which indicate that these biomasses are highly reactive. In study Cardozo *et al.* (2014) was compared the combustion of different agricultural residues in a single unit designed for wood pellets. In study McKechnie *et al.* (2016) was investigated life cycle environmental (greenhouse gas (GHG) and air pollutant emissions) and financial implications of electricity generation from steam-treated pellets, including fuel cycle activities (biomass supply, pellet production, and combustion) and retrofit infrastructure to enable 100% pellet firing at a generating station that previously used coal. Impacts of retrofit infrastructure become increasingly significant at lower generating station capacity factors, further favoring steam-treated pellets for both environmental and financial metrics (McKechnie *et al.*, 2016). In study Nilsson *et al.* (2011), the costs and energy requirements for the production of pellets from agricultural raw materials were analyzed. The energy use in manufacturing pellets from air-dried crops was generally no higher than when moist sawdust was used as the raw material. The objective of work (Carvalho *et al.*, 2013) was to evaluate the technical and environmental performance of a 15 kW pellet boiler when operated with different pelletized biomass fuels, namely straw (*Triticum aestivum*), Miscanthus (*Miscanthus _ giganteus*), maize (*Zea mays*), wheat bran, vineyard pruning (from *Vitis vinifera*), hay, Sorghum (*Sorghum bicolor*) and wood (from *Picea abies*) with 5% rye flour. The investigation in the international market shows that mixed biomass pellets are promising fuels and with the appropriate support these fuels have many prospects for the future (Karkania *et al.*, 2012). The use of biomass pellets would not only create new market opportunities for agricultural industries, it would also reduce dependence on coal, as well as the greenhouse gas emissions associated with coal use (Karkania *et al.*, 2012). In paper Tauro *et al.* (2018) was examined the potential for biomass pellets to become a sizable low-carbon, renewable energy source that could compete with and substitute fossil fuels in specific economic sectors in Mexico where it was estimated that the market energy potential for pellets from currently available agricultural and forest residues in Mexico is between 131 and 233 PJ/yr, with total costs ranging from 6.3 to 12.8 USD/GJ. In paper (Dai *et al.*, 2015), a ceramic foam burner with embedded alumina pellets was designed, which set different shapes of tubes by taking can advantage of the discrete pellets. An experimental system was built to study the effects of the pellet diameter and pellet location on the combustion of low-concentration coal mine methane (LCM) (Dai *et al.*, 2015). Results indicates that the heat transfer features of 13-mm pellets are more similar to those of 10-PPI ceramic foam compared with 6-mm pellets and 9-mm pellets (Dai *et al.*, 2015). The combustion performance in a double-layer burner packed with alumina pellets of different diameters was experimentally studied in article (Gao *et al.*, 2012). In study Qu and Feng, (2015), methane/air combustion in a two-zone catalytic alumina pileup-pellets burner with equivalence ratios varying from 0.55 to 0.70 was researched. Torrefied biomass has several benefits, such as higher energy density, good grindability, higher flowability and uniformity (Li *et al.*, 2012). The outlet of a mechanical biological treatment plant for mixed municipal solid waste is further processed to produce RRBf (Refined Renewable Biomass Fuel) within the frame of the EU Life project MARSS (Material Advanced Recovery Sustainable Systems) (Schulzke *et al.*, 2017). In paper Dasappa *et al.* (2004) addresses case studies of a low temperature and a high temperature industrial heat requirement being met using biomass gasification (Dasappa *et al.*, 2004). In paper Verma *et al.* (2017) provides a detail review on the need of drying of biomass before co-firing, different technologies used for biomass drying, biomass co-firing to the existing coal fired power plants and the environmental benefits of biomass co-firing. In paper Hosier and Svenningsson, (1987) was presented the social and economic analysis of an evaluation of biomass briquettes as a substitute for charcoal.

Coal powder is residue in mines with economic value but is regarded as waste and not used. We have produced machine for binding together the coal powder particles and producing the tablets. Process is completely automatic. Other materials (feedstock) can be used instead the coal. Documentation and machine are available in our lab.

Materials and Methods

Biomass Waste Management

According to the European Union standardization there are five procedures in the biomass waste treatment process:

1. Eco-design,
2. Biomass waste decreasing,
3. Biomass waste reusing,
4. Recycling and making compost,
5. Energy from biomass waste,
6. Biomass waste disposing.

In order to optimize the system for biomass waste management based on decreasing of pollution of life environment and for the cheapest solution there is goal to develop the biomass waste management process. This innovative solution could lead to revolution in the biomass waste issue. By entering of the main data for biomass waste, quantity and composition for the some region, the client could know which is the best solution for the biomass waste treatment and transport for the region. Several biomass waste treatments are included:

Manufacturing, Applications and Mechanical Properties of Lightweight Wood-Based Sandwich Panels

Khameel B Mustapha, University of Nottingham (Malaysia Campus), Semenyih, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Civilizations, irrespective of their temporal locations on the timeline of human existence, strive on the availability of energy in its various guises. As a prime measure of standard of living, the amount of energy consumption typically correlates with the degree of civilization (Holdgate, 1987). It is therefore unsurprising that as civilizations bask in the glory of progress, the progress typically rides on the wave of increased energy usage. The consequence of this state of affairs is the amplification of stress on the environment, the pernicious impact on the ecosystem and the ever increasing pressure on the biosphere (e.g., desertification, water and air pollution, climate variability, global warming etc.). The recognition of these eco-concerns has morphed into global and local policy proposals that: (a) seek long-term global environmental strategies for achieving sustainable development; and (b) intensifies the quest for more sustainable energy systems (Bakshi and Fiksel, 2003; Anon, 2001). Although the recent proliferation of green technologies has been largely driven by the implementation plans for the alternative energy dimensions, a shift in material consumptions offers a promising route for the switch towards low-carbon product designs and development (Anastas and Zimmerman, 2006). In the light of the preceding reasons, the focus of many sustainable development initiatives centres on efficient management of natural resources through the reduction of the environmental impact of materials and manufacturing technologies (Koltun, 2010).

Historically, an array of natural materials such as bone, wood and shell facilitated the survival and development of humanity in early stages. However, these materials were pushed out of fashion by synthetic counterparts that seemingly offered improved performance. Yet, these natural structures, are endowed with distinct combinations of physico-mechano-chemical properties that often surpass those of synthetic counterparts by orders of magnitude. As such, natural materials continue to inspire generations of scientists and engineers. Indeed, in recent years, tremendous research efforts have gone into studying how the design of biological cellular structures of living organisms can influence the design of advanced composite materials for multifunctional capabilities (Chen and Wu, 2013; Verma and Tomar, 2014; Wegst *et al.*, 2015). Along this direction, sandwich composites resembling low-density natural cellular materials have emerged as good candidates for lightweight design technologies with applications in various industries (Schaedler *et al.*, 2011; Zenkert, 1995).

Sandwich structures embody a variant of laminated composites. They comprise three primary parts (a pair of thin skins, a thicker less-dense core, and thin layers of coupling agents) as shown in Fig. 1. In terms of development, wood-based sandwich structures initially lagged behind many of the competing sandwich structures derived from other types of materials. Nevertheless, recent developments have propelled them for use as primary elements in lightweight transport infrastructures, naval shipbuilding, prefabricated shelters, as well as insulation for thermal comfort (Kawasaki and Kawai, 2006; Li *et al.*, 2014). Clearly, the increasing use of these structures hinges on two advantages, among many. First, the use compensates for the scarcity of first-generation raw wood resources as a result of monstrous deforestations. Second, it alleviates the problem of poorer quality of wood products from less mature trees.

Fig. 1 Schematic of wood-based sandwich structures with wooden skin and wooden core.

The combination of materials for wood-based sandwich structures (WBSS) is diverse, but four broad groups can be defined: (i) WBSS with non-wooden skins separated by a wooden core; (ii) WBSS with non-wooden skins separated by a hybrid wooden composite; (iii) WBSS with wooden skins separated by a non-wooden core; and (iv) WBSS with wooden skins separated by a wooden core. Among these competing types of WBSS, the last group qualifies as the “greenest”. It is therefore the focus of this article to examine the manufacturing, applications and properties of the last group (i.e., the wooden skins/wooden core WBSS).

Lightweight Wood-Based Sandwich Structures

Manufacturing Methods

The manufacturing of sandwich structures is easily influenced by several factors. Structural performance requirement, the volume of production, and the cost of tooling are some of the notable ones. Commercial-grade productions of wood-based sandwich structures rely on a series of proprietary steps and materials. However, the production of prototype sandwich structures routinely embraces the selection of the skin and core materials, the strength requirement of the bonding agent, pressing and finishing. [Fig. 2](#) features some of the common methods of interests in the manufacturing of sandwich structures ([Manalo et al., 2016](#)).

The steam-assisted hot pressing method was used for the construction of wood-based sandwich structures in the earlier studies by [Kawasaki et al. \(2006\)](#).

Skin materials

The top and bottom skins sustain the structural strength and stiffness of the WBSS. The skin materials can be purchased off-the-shelf commercially, since these can often be veneers or products derived from veneers, such as plywood, oriented strand board (OSB), and laminated veneer lumbers (LVL), among the many options that fit this purpose. These products have well-documented methods of productions that are now part of standard literature. For instance, a highlight of the steps in the production of plywood is illustrated in [Fig. 3](#), as expounded in [Hughes \(2015\)](#). A simplified production method of wavy plywood for shipbuilding applications is described by [Francesco et al. \(2011\)](#).

Core materials

The core contributes to the shear rigidity of the WBSS. The core could be random, periodic or hybrid in nature. Random cores are mostly derived from foam-based materials, while periodic cores could take the form of paper honeycomb, or laminated paper (corrugated, or truss). Balsa wood, cork, fibreboard, and many agricultural residues (e.g., flax mat, jute fibres, kenaf fibres etc.) are examples of common materials that have been used for the core of WBSS ([Kawasaki et al., 2003](#); [Dweib et al., 2004](#); [Lakreb et al., 2015](#)). Balsa wood is particularly good for marine applications. For lightweight WBSS, the production of cores derived from fibreboard provides an effective mean of controlling the weight and density of the final product. The construction of WBSS with plywood skins and fibreboard derived from radiata pines was extensively investigated by [Kawasaki et al.](#) in a series of studies that concentrated on their use for in-plane shear loading and thermal insulation capabilities ([Kawasaki et al., 2003, 1998, 1999](#)). With intent on applications for cladding and wind load carrying purposes, [Fernandez-Cabo et al. \(2011\)](#) constructed, simulated and tested specimens of WBSS with OSB skins and fibreboard cores. [Fig. 4](#) portrays a sample industrial set-up for the production of fibreboards. The key raw materials being wood waste, sawdust, recycled wood pellets etc. Other types of agricultural non-wood residues can also be used as demonstrated by [Dweib et al. \(2004\)](#). The resin content in the mixing stage of the production could be polymeric isocyanate. Normally, the quality of the final fibreboard product depends on the processing parameters as enunciated in the comprehensive report by [Kelly \(1977\)](#), of the United States Department of Agriculture (USDA) Forest Services. Nevertheless, fibreboards formed from small fibres have been shown to possess better mechanical and dimensional properties than those made from large fibres ([Kawasaki et al., 1998](#)).

Fig. 2 Methods of manufacturing sandwich structures.

Fig. 3 A summary of key steps in the production of plywood.

Fig. 4 A simple set-up for the production of fibreboard.

Although fibreboard represents an excellent core material because of its low thermal conductivity and the ability to control its density easily, balsa wood has emerged as another worthwhile alternative for WBSS. Balsa (*Ochroma pyramidale*) is the softest commercial hardwood (EOL, 2018). It is native to South America (Ecuador being the largest commercial supplier), but also found in Solomon Island, Indonesia, Papua New Guinea and Thailand. Osei-Antwi *et al.* (2013) investigated the shear stiffness/strength of panels derived from cubes of South American balsa as core materials for sandwich structures. Kotlarewski *et al.* (2016) compiled the mechanical properties of balsa from Papua New Guinea. A comparative study of the two investigations established that the set of specimens from Papua New Guinea exhibits lower density, better shearing strength as well as better modulus of rupture, making them superior to those from South America.

Bonding

Bonding operation is a major step in the production of the WBSS, and a classic reference on this is the report by Selbo (1975), also of USDA. Although the bonding can be facilitated by a cold or hot pressing process, the injection of steam in the steam-assisted process facilitates a faster operation and high-quality end products. Still, it is advised to abide by the specific recommendations of adhesive manufacturers in applications for sandwich constructions. Some key factors to consider in choosing adhesives include the type of applications (structural/non-structural, interior/exterior), resistance to heat and humidity etc. For laboratory-scale productions of WBSS, means of application of adhesives could be through glue spreader, portable sprayer, precision dispensing kit, and painting brush.

Properties

Investigations into the mechanical behavior of sandwich structures have been dominated by measurements of their flexural and compressive properties, impact and ballistic responses as well as acoustic and shear properties. Assessment of these properties and comparison with conventional materials facilitate the possibility of determining the usefulness of a given sandwich material. In principle, the attendant mechanical properties of a specific WBSS will depend to a large extent on the properties of the components from which it is made. For instance, the density of a WBSS will be a function of the densities of the face skins and the core. It is recommended the measurements of these properties be based on the several international standards developed for this purpose. Among the standards are:

- ASTM Standard C271 for determination of density of sandwich core materials,
- ASTM Standard C273 for determination of shear properties of core materials,
- ASTM Standard C364 for determination of edgewise compressive strength,
- ASTM Standard C393 for determination of core shear properties by beam flexure,
- ASTM Standard D7250 for determination of flexural and shear stiffness,
- JIS A 5908:2003 for testing of fibreboard,
- PN-EN ISO 14125:2001 for flexural test of sandwich panels,
- French standard for bending, shear and compression of particleboard.

These standards stipulate the factors such as shape, dimensions of samples, the essential conditions for conducting the test measurements, and procedures for analysing the obtained results. It is generally common to conduct flexural tests by means of the well-known 3-point or 4-point bending tests. Extensive experimental investigations on WBSS have been performed by [Kawasaki et al. \(2003, 1998, 1999\)](#) and [Fernandez-Cabo et al. \(2011\)](#), who investigated the in-plane shear, bending and thermal insulation properties of WBSS using a variety of standard methods used for testing construction materials. The bending and shear properties of WBSS with marine plywood skins and plywood honeycomb core were reported by [Francesco et al. \(2011\)](#). Two recent studies on the subject matter include [Jin et al. \(2015\)](#) and [Lakreb et al. \(2015\)](#). **Tables 1–3** summarise the range of mechanical properties reported by the aforementioned studies.

Table 1 Shear properties of selected WBSS

Applications

WBSS have applications that are similar to those of the general sandwich structures, especially for use as prefabricated building elements (Davies, 2008). When used as the core materials, the porosity of wood fiber presents acoustic insulation benefits (Fernandez-Cabo *et al.*, 2011), making WBSS suitable in homes and buildings where one wishes to eliminate noise and sound transmission from room to room or as modular separating walls in trade fairs construction. Other potential usages pertains to packaging for flight and cargo containers, furniture, naval shipbuilding, flooring etc.

Materials, Design and Development of Latent Heat Storage Systems for Medium and Large-Scale Applications: Issues and Challenges

Palanisamy Muthukumar and Hakeem Niyas, Indian Institute of Technology Guwahati, Guwahati, India

Introduction

Energy plays a vital role in the development of all nations. The majority of the world's current energy consumption is met by the non-renewable energy sources, which occupies a huge proportion of 80.7% (REN21, 2017). If we continue to rely on the non-renewable energy sources at the same pace for another century, we will have exhausted most of these resources. Opting for renewable energy is one of the strategic solutions to avoid the growing imbalance of available resources. Of the several renewable energy sources, solar energy is the best in terms of available energy potential. Traditionally, solar energy is used in heating and drying applications. Nowadays, it finds a remarkable place in the field of electricity generation. Solar energy can be converted to electricity, directly using photovoltaics (PV), or indirectly using concentrated solar power (CSP).

Thermal Energy Storage

Photovoltaics convert the sunlight into electric current using the photoelectric effect. CSP plants use reflective lenses or mirrors and tracking systems to focus a large amount of sunlight into a small point or beam by which the working fluid gets heated to a higher temperature. In direct steam generation (DSG) plants, the working fluid is generally water and the steam produced is directly fed to the turbine for electricity production. In non-DSG plants, the primary working fluid is generally a synthetic oil that gets heated from the concentrated sunlight. Synthetic oil transfers the heat to the secondary working fluid (water/steam), which is then supplied to the turbine for power generation. The major disadvantage with the PV and CSP plants is the inability to generate electricity during night and overcast day, which reduces the operating time. Perhaps this issue can be solved in CSP plants by incorporating thermal energy storage (TES). In addition, TES systems can increase the plant reliability and reduce the levelized cost of energy. Thermal energy can be stored in the form of sensible, latent and thermo-chemical heat. In sensible heat storage (SHS) method, thermal energy is stored in the storage material by raising the temperature. In latent heat storage (LHS), thermal energy is stored by phase change of material, e.g., solid to liquid. In thermo chemical heat storage (THS), thermal energy is stored during the reversible chemical reactions.

TES system employed in CSP plants can be classified as active or passive systems. An active storage system is mainly characterized by the forced convection heat transfer of the storage material. The storage material itself circulates in the main circuit of the CSP plant. This system uses one or two tanks as storage media. Active systems are subdivided into direct and indirect systems. In a direct system, the heat transfer fluid (HTF) serves also as the storage medium, while in an indirect system, a second medium is used for storing the heat. Steam accumulators falls under the category of active storage system and are especially suited to meet the requirements for buffer storage in solar steam systems, providing saturated steam at pressures up to 100 bar. The main disadvantages of active systems are, it requires bulky containers for accommodating the storage materials and necessitates proper control systems to avoid freezing of the storage material during night. Oro *et al.* (2012) reported that the commonly used two tanks molten salts storage system is the one with the higher environmental impact and therefore, should be substituted by the other systems.

In passive heat storage system, the storage material is a fixed entity and HTF passes through the storage medium and exchanges heat during charging and discharging cycles. Passive storage systems are mainly solid storage systems (concrete for SHS, PCM for LHS and metal hydrides for THS). In general, the passive storage system consists of a regenerator type heat exchanger wherein the HTF passes through the storage media for charging and discharging only. During charging, the high-temperature HTF transfers heat to the storage medium. The stored energy is released during discharging as the low-temperature HTF passes through it. Fig. 1 depicts the schematic representation of a CSP plant with TES system.

Phase Change Materials

Phase change materials (PCMs) are a group of families of materials, which will undergo a phase change while heating/cooling it above/below the phase transition temperature. Initially, the PCMs act like SHS materials; their temperature increases as they absorb heat. However, when PCMs reach the phase transition temperature, they absorb a large amount of heat (called as latent heat) at a near constant temperature. The PCM continues to absorb heat without a significant increase in temperature until all the material has transformed to the liquid phase. Once the entire PCM is melted, the temperature of the PCM again increases when heat is supplied to it. PCMs are broadly classified into inorganic, organic and eutectics. Inorganic PCMs generally include hydrated salts and metals, which are suitable for medium to high temperature storage applications such as process industries and thermal power plants. Organic PCMs on the other hand include paraffins and fatty acids, which are normally used in thermal comfort in buildings, preservation of food/medicines, cooling of electronics, etc. Eutectics are compounds formed by mixing two or more

Fig. 1 Schematic view of a CSP plant with TES system.

PCMs (organic or inorganic) which melts/solidifies in the same temperature interval. A large number of PCMs are available in any required temperature range.

The main criteria that govern the selection of PCMs are (Abhat, 1983):

1. Possess a phase transition temperature in the desired operating temperature range.
2. Have a high latent heat of fusion, so that a smaller amount of PCM can store the desired amount of energy.
3. Possess high specific heat to provide additional SHS effects.
4. Have a high thermal conductivity for faster charging and discharging rates.
5. Small volume changes during phase transition, so that a simple type of heat exchanger can be used.
6. Exhibit little or no sub-cooling during freezing.
7. Possess chemical stability, no chemical decomposition.
8. Should not contain poisonous, flammable and explosive elements/compounds.
9. Exhibit little or no corrosion.
10. Available in large quantities at a cheaper cost.

Commercialization of LHS System

The most intensely studied LHS system among various configurations is the shell-and-tube system. In the shell-and-tube configuration, PCM is usually filled in the shell, and the HTF flows through the tubes. Avci and Yazici (2013) performed an experimental study for evaluating TES characteristics of paraffin in a horizontal shell-and-tube storage unit. They found that the temperature field is radially uneven during the melting process in the horizontal annulus due to natural convection. Trp *et al.* (2006) studied the storage phenomenon during melting and solidification of paraffin in a vertical shell-and-tube LHS storage unit. They reported that the temperature distribution in the PCM is non-isothermal during melting and isothermal during solidification. Agyenim *et al.* (2010) experimentally studied the effect of using multiple HTF tubes in shell-and-tube LHS units. The multi-tube system showed superior performance than the single tube system aided with the distribution of heat in multiple layers around each HTF tube to the PCM. Certain numerical studies also portrayed the advantages of using multiple tubes in LHS systems. Esapour *et al.* (2016) developed a 2D numerical model to study the influence of the number of HTF tubes in an LHS system during the charging process. They reported that by increasing the number of HTF tubes, the bottom region of the shell is influenced by the additional heat transfer surface thereby reducing the total melting time by about 29% for the four tubes system. In a more recent experimental work by Allouche *et al.* (2015), the performance of a microencapsulated PCM in a tube-bundle heat exchanger for low-temperature TES was studied. When compared the results with previously published results for other configurations, the tube-bundle storage tank configuration was found to perform better than a coil-in-tank configuration. They also mentioned that shell-and-tube type of heat exchanger has the additional advantage of incorporating fins to the HTF tubes, which can significantly enhance the heat transfer. Though several prototypes of TES were developed across the world, only a few large-scale TES systems have been commissioned in the CSP plants (Gil *et al.*, 2010). There are about 101 operational CSP plants in the world working on technologies such as linear Fresnel reflector, parabolic trough and solar tower. Of these, only 41 CSP plants have added commercial storage systems to the utility. Two-tank molten salt storage system is the highly installed TES system, which has its presence in 31 CSP plants (NREL, 2017). Tables 1 and 2 present the details of the CSP plants with and without 2-tank molten storage system. Though, the passive storage systems have several potential benefits, it has not yet commercialized till date. An attempt has been made in the present work to commercialize the LHS system by studying the performance characteristics of the LHS system through thermal models and experimental investigations using a lab-scale LHS prototype of 10 MJ storage capacity. Based on the results of the thermal model and experimental investigations, the study has been extended to develop an industrial-scale LHS

prototype of 0.25 GJ storage capacity and integrate it with a commercial steam accumulator of 1 GJ storage capacity. This combined storage system has been installed in the LFR based pilot-CSP plant in Vallipuram, Tamil Nadu, India.

Lab Scale Prototype – Design, Thermal Modeling and Numerical Results

Design and optimization of LHS prototypes require an exhaustive analysis of the heat transfer characteristics, between the PCM and HTF. The number of the HTF tubes and fins on the HTF tube's outer surface play a significant role in transferring the heat between them. Un-optimized prototype with more number of the HTF tubes and fins would lead to higher material inventory. Additionally, the overall weight of the system will increase too. Hence, a detailed optimization study is needed to have a cost-effective LHS system. To achieve this, many experiments with different geometric configurations, by varying the number of the HTF tubes and fins, need to be conducted. This approach has two major disadvantages; (i) the development cost of the different prototypes to be tested is high and (ii) for up scaling, new prototypes need to be developed for getting the optimized module. Development of a numerical tool for the optimization of geometric configuration and performance evaluation of LHS prototype is an ideal solution to overcome the above limitations. But the mathematical modeling of the LHS prototypes, especially in the multidimensional case is complex (Bonacina *et al.*, 1973). The major problems involved in the modeling are (i) inclusion of latent heat of PCM, (ii) natural convection of the melt and (iii) conjugate heat transfer between the PCM and HTF. This section presents a 3D transient numerical model, which is developed using the effective heat capacity (EHC) method to study the performance characteristics of a shell-and-tube type lab-scale LHS prototype of 10 MJ LHS capacity. Longitudinal fins adopted for heat transfer enhancement in the experimental studies are also included in the numerical model. Optimization of the number of tubes and fins for the LHS system is performed using a 2D transient model, the output (the number of tubes and fins) of which is used in the 3D model. A eutectic ternary mixture comprising of potassium nitrate, sodium nitrate and sodium nitrite in the weight proportion of 53:7:40, which has the melting point of approximately 142°C is selected as the PCM for the numerical simulation. Hi-Tech Therm 60, a synthetic thermic oil is selected as the HTF. The thermo-physical properties of the selected PCM (Bohlmann, 1972) and HTF are given in Tables 3 and 4.

Design Methodology

The lab-scale prototype is designed for an LHS capacity of about 10 MJ. The volume (V) of PCM required depends on the heat storage capacity (Q), density (ρ) and latent heat of fusion (L_f). For storing a heat of 10 MJ, the PCM volume required is calculated

Table 3 Thermo-physical properties of the PCM

Properties	Values
Latent heat of fusion (kJ kg^{-1})	81.5

using Eq. (1). Based on the volume found, the inner diameter of the shell (D) is calculated using Eq. (2). The outer diameter (d) and thickness of HTF tubes are 12.7 mm and 2 mm. The height (h) and thickness (b) of the longitudinal fins attached to the tubes are 10 mm and 1 mm. The number of HTF tubes and fins were optimized based on the discharging time. The number of HTF tubes (N_T) and fins (N_F) on each tube in the optimized lab-scale LHS prototype are 25 and 4. The HTF tubes and fins are made of copper. The outer shell of the prototype is made of stainless steel (SS304) of diameter 335 mm OD and 5 mm thickness.

$$Q = \rho V L_F \quad (1)$$

$$V = \left[\frac{\pi}{4} (D^2 - N_T d^2) - N_T N_F b h \right] L \quad (2)$$

Model Description

Fig. 2 shows the sectional view of the 3D shell-and-tube type LHS model containing a PCM in the shell region and HTF in the tube region, both separated by HTF tubes. The LHS unit is divided into three cartridges, separated by a thin layer of concrete. To study the thermal storage behavior of a shell-and-tube type LHS prototype, four physical processes have to be simulated, i.e., HTF flow, conduction, convection, and phase change. The thermal model is developed based on following assumptions:

- HTF is incompressible and Newtonian.
- HTF flow is laminar and exhibits negligible viscous dissipation.
- The initial temperature of PCM is uniform.
- Phase change during melting/solidification occurs in a temperature interval.
- Thermal losses through the outer wall of the PCM are negligible.

Governing Equations

The thermal model developed is based on a conjugate heat transfer problem, which simultaneously solves the flow behavior of HTF and phase change behavior of PCM. The biggest problem associated with adapting an existing sensible heat based model for an LHS model is the incorporation of latent heat required to melt/solidify the PCM. This issue is solved by using the EHC method, which includes both specific heat and latent heat of the PCM in a single term called EHC. The EHC method was developed by Bonacina *et al.* (1973) and later used by several authors with slight improvements. The heat capacity of the PCM is modified as shown in Eq. (3) and the EHC is calculated using Eq. (4). Phase change is considered to occur during a temperature interval. Problems of this type are often referred to as mushy region problems. The discontinuous modified heat capacity is implemented in the COMSOL Multiphysics software using a smoothed Heaviside function with a continuous second derivative. Accordingly,

Fig. 2 Computational model of the LHS prototype. Reproduced from Niyas, H., Prasad, S., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Numerical results. *Energy Conversion and Management* 135, 188–199.

continuity, momentum, and energy equations are given in Eqs. (5)–(7). The effect of convection heat transfer is taken care by the material derivative term DT/Dt in Eq. (7). To include the effect of buoyancy and reduce the complexity in solving the Navier-Stokes equations, Boussinesq approximation is added to the momentum equation, which is given by Eq. (8). To nullify the velocities in the solid region of the PCM, Darcy law's source term is added to the momentum equation, which is given by Eq. (9).

$$C_p = \begin{cases} C_{p,s} & \text{for } T < T_s \\ C_{p,eff} & \text{for } T_s \leq T \leq T_L \\ C_{p,L} & \text{for } T > T_L \end{cases} \quad (3)$$

$$C_{p,eff} = \frac{C_{p,s} + C_{p,L}}{2} + \frac{L_F}{T_L - T_s} \quad (4)$$

$$\nabla \cdot \vec{v} = 0 \quad (5)$$

$$\frac{\partial \vec{v}}{\partial t} + (\vec{v} \cdot \nabla) \vec{v} = \frac{1}{\rho} (-\nabla P + \mu \nabla^2 \vec{v} + \vec{F} + \vec{S}) \quad (6)$$

$$\rho C_p \frac{DT}{Dt} = k \nabla^2 T \quad (7)$$

$$\vec{F} = \rho \vec{g} \beta (T - T_M) \quad (8)$$

$$\vec{S} = \frac{(1 - \theta)^2}{(\theta^3 + \varepsilon)} A_{MUSH} \vec{v} \quad (9)$$

$$\theta = \frac{T - T_s}{T_L - T_s} = \frac{T - T_M + \Delta T_M}{2 \Delta T_M} = \begin{cases} 0 & \text{for } T < T_s \\ 0 - 1 & \text{for } T_s \leq T \leq T_L \\ 1 & \text{for } T > T_L \end{cases} \quad (10)$$

The mushy zone constant defines the transition of velocity in the mushy region. Mushy zone constant values between 10^3 and 10^7 are recommended for most computations. Here, a value of 10^4 is taken based on the works presented by Kheirabadi and Groulx (2015) on the effect of mushy zone constant. During charging cycle, the Darcy law's source term dominates all other terms in the momentum equations and forces the predicted velocities to near zero before melting of the PCM. Once a molten layer of the PCM is formed, the melt fraction of the PCM increases and hence the source term decreases. After complete melting of the PCM, the melt fraction becomes unity, and therefore the source term becomes zero. The momentum equations then behave normally in terms of actual fluid velocities. Similarly, during the discharging cycle, where the local melt fraction assumes a value of 1 initially, the source term is zero and the momentum equations are in terms of actual fluid velocities. Once the solidification of PCM is started, the source term increases and approximates the Darcy law in the mushy region. Finally, the Darcy law's source term dominates all other terms in momentum equations and forces the predicted velocities to near zero at the end of the discharging cycle.

Performance Parameters

Melt fraction

Most of the PCMs, especially a mixture of salts, often melt over a finite temperature range. The temperature range wherein, the melt exists in both solid and liquid phases is generally called mushy zone. The highest temperature at which, the material is completely in the solid state is called solidus temperature and the lowest temperature at which, the material is completely in the liquid state is called liquidus temperature. Melt fraction is a non-dimensional parameter, which quantifies the percentage of liquid phase in the

marshy region. Melt fraction of the PCM can be calculated based on the lever rule applied between the solidus and liquidus temperatures and it is given by Eq. (10).

Charging/discharging time

Charging/Discharging time of LHS prototype is defined with respect to the temperature rise/decrease of PCM. The LHS prototype is said to be fully charged/discharged when the entire PCM is melted/solidified, i.e., when the melt fraction reaches a value of unity/one. The LHS prototype should be designed and optimized in such a way that, it possess a lesser charging and discharging times.

Energy stored/discharged

Energy gets stored/discharged in the PCM in two forms during charging, viz. sensible and latent heat. Initially, when the PCM is in the solid state, the storage/discharge rate through sensible heat would be greater than that of latent heat, due to the higher temperature difference between the initial temperature and solidus/liquidus temperature of the PCM. Sensible, latent and total heat stored/discharged in the PCM during the charging/discharging process can be calculated using the Eqs. (11)–(16), respectively.

$$E_{S,C} = m [C_{ps} (T - T_m) + C_{pl}(T_m - T_{ini})] \quad (11)$$

$$E_{L,C} = m L_F \theta \quad (12)$$

$$E_{T,C} = m [C_{ps} (T - T_m) + L_F \theta + C_{pl}(T_m - T_{ini})] \quad (13)$$

$$E_{S,D} = m [C_{ps} (T_{ini} - T_m) + C_{pl}(T_m - T)] \quad (14)$$

$$E_{L,D} = m L_F (1 - \theta) \quad (15)$$

$$E_{T,D} = m [C_{ps} (T_{ini} - T_m) + L_F (1 - \theta) + C_{pl}(T_m - T)] \quad (16)$$

Results and Discussions

In the following sub-sections, optimization of the LHS prototype, validation, grid independent test and various results obtained from the numerical simulations of the lab-scale LHS prototype during charging and discharging processes are presented.

Optimization of tubes and fins

The major constraint of PCMs is its lower thermal conductivity, which necessitates the implementation of heat-transfer enhancement techniques such as finned tubes. Increasing the number of tubes and fins on the tubes outer surface increases the overall heat-transfer surface area of the system. To optimize the number of tubes and fins in the LHS prototype, a 2D thermal model is developed based on the governing equations, Eq. (5)–(7) to compare the performances of the selected systems, viz. models with 19, 22, 25 and 28 tubes and 25 tubes model with 0, 2, 4 and 6 fins. To maintain the same PCM volume in the various models, the shell diameter is kept different in the models. The shell diameter values of various models are given in Tables 5 and 6. Figs. 3 and 4 show the various models considered for optimization. The optimization is done based on the discharging time, as

Table 5 Optimization of tubes

No. of tubes	Shell diameter (mm)	Charging time (min)	% reduction in time	Discharging time (min)	% reduction in time
19	318.9	184		262	
22	319.6	166	9.8	210	19.8
25	320.4	151	9.0	180	14.3
28	321.1	138	8.6	165	8.3

Fig. 4 Optimization of fins (a) no fins, (b) 2 fins, (c) 4 fins and (d) 6 fins. Reproduced from Niyas, H., Prasad, S., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Numerical results. *Energy Conversion and Management* 135, 188–201.

discharging is a comparatively slower process than charging. The discharging time of different configurations is given in **Tables 5** and **6**. It can be seen from **Table 5** that there is a vast reduction in the discharging time of LHS prototype (19.8%) with 22 tubes when compared to 19 tubes and 25 tubes when compared to 22 tubes (14.3%). However, there was only a marginal reduction in the discharging time of LHS prototype with 28 tubes when compared to 25 tubes (8.3%). Similarly, it can be seen from **Table 6** that there is a vast reduction in the discharging time of LHS prototype (29.4%) with 2 fins when compared to 0 fins and 4 fins when compared to 2 fins (21.3%). However, there was only a marginal reduction in the discharging time of LHS prototype with 6 fins when compared to 4 fins (9.0%). Hence, shell-and-tube type heat exchanger with 25 tubes and 4 fins attached to each tube is found to be the optimized configuration for the current heat storage/discharge requirement.

Model validation

To validate the developed thermal model for the charging and discharging process, the results obtained for the temperature variation of the PCM at 2 locations in the LHS prototype, viz. middle of 1st and 3rd cartridges [B (–141 mm, 30 mm)] were compared with the corresponding temperature values of the experiments. The thermocouple position selected for validation is point B, which is shown in **Fig. 5(a)**. The PCM is initially at 122/162°C during the charging/discharging process. At any time $t > 0$, the inlet of the tubes is given an HTF flow of 0.3 m³/h and inlet temperature of 162/122°C during the charging/discharging process. **Fig. 5(b)** and **(c)** illustrates the comparison between the experimental and numerical values for the charging and discharging processes. It can be noted from **Fig. 5(b)** and **(c)** that there is a close agreement between the experimental and numerical data. The maximum deviation is about 3.36°C and 2.74°C during the charging and discharging processes, respectively.

Grid independent test

To test the dependency of numerical results on the mesh element size, simulations with different mesh element sizes were run for charging and discharging processes. **Fig. 6(a)** and **(b)** shows the average temperature variation of the LHS prototype with a different number of mesh elements viz. 786,342, 890,548 and 995,643 elements for charging process and 743,148, 842,412 and 944,674 for discharging processes. It can be observed from **Fig. 6(a)** and **(b)** that the charging/melting simulation demands more number of mesh elements, due to the free convective movement of the PCM.

For all the cases of grid independent test, the PCM is initially at 122/162°C during charging/discharging process. At any time $t > 0$, the inlet of the tubes is given an HTF flow of 0.3 m³/h and inlet temperature of 162/122°C during charging/discharging process. It is observed from **Fig. 6(a)** and **(b)** that the models with 890,548 and 842,412 elements are found to be grid independent for charging and discharging processes.

Temperature variation

Fig. 7 depicts the average temperature variation of the LHS prototype during the charging and discharging processes. The average temperature is the volumetric average temperature of all the mesh elements of the numerical model. Initially, the LHS prototype is

Fig. 5 Model validation (a) thermocouple position, (b) charging and (c) discharging. Reproduced from Niyas, H., Prasad, S., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Numerical results. *Energy Conversion and Management* 135, 188–202.

at 122/162°C during the charging/discharging process. When the HTF at 162/122°C is passed through the HTF tubes, heat transfer takes place between the HTF and PCM. It can be noted from Fig. 7 that the initial part of the average temperature variation curve shows a steady increase/decrease of temperature during charging/discharging process. This steady increase/decrease is due to the higher heat transfer potential available during the initial period of the processes. After 30 min, the slope of the temperature variation curve started reducing. During this time, LHS prototype stores/discharges a large amount of latent heat. The PCM average temperature reaches approximately about 161/132.3°C in 150/165 min during the charging/discharging process. The PCM temperature increase during charging is faster than the PCM temperature decrease during discharging. This is mainly due to the additional convective heat transfer that increases the heat transfer rate of the prototype during the charging process.

Charging/discharging time

Fig. 8 shows the average melt fraction variations of the LHS prototype during the charging and discharging processes. Average melt fraction is the volumetric average melt fraction of all the mesh elements of the numerical model. Melt fraction is a critical performance parameter, which depicts only the latent heat storage/discharge characteristics during the charging/discharging process. It can be seen from Fig. 8 that the trend of increase/decrease of average melt fraction during charging/discharging process is initially faster due to the higher heat transfer potential and slower after a certain period due to the lower heat transfer potential

Fig. 6 Grid independent test of the shell-and-tube model (a) charging and (b) discharging. Reproduced from Niyas, H., Prasad, S., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Numerical results. *Energy Conversion and Management* 135, 188–203.

Fig. 7 Average temperature variation of the shell-and-tube LHS model. Reproduced from Niyas, H., Prasad, S., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Numerical results. *Energy Conversion and Management* 135, 188–204.

between the HTF and PCM. It took about 137/158 min for the LHS model to get completely charged/discharged. However, the charging/discharging time of the LHS model with respect to the actual thermocouple locations of the prototype is 111/117 min.

Melt fraction

Fig. 9(a) and **(b)** depicts the average melt fraction contours of the LHS prototype during the charging and discharging processes. It can be seen from **Fig. 9(a)** and **(b)** that the average melt fraction of the LHS prototype is 0/1 at the start of the charging/discharging processes ($t=0$ min). At time $t=50$ min, it can be noted that the 1st cartridge is almost fully charged during the charging process. However, during the discharging process at the same time, the 1st cartridge is discharged to a limited extent only and not fully as in the case of charging. Hence, the charging process is faster than the discharging process.

Fig. 8 Average melt fraction variation of the shell-and-tube LHS model. Reproduced from Niyas, H., Prasad, S., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Numerical results. *Energy Conversion and Management* 135, 188–205.

This is mainly due to the additional natural convection heat transfer present in the charging process. The effect of natural convection can be clearly seen in the LHS prototype during charging process ($t=50$ min, 100 min) from the asymmetric variation of the melt fraction. Similar melt fraction variation is not noticeable in the discharging process as it is a conduction-dominated process. It can be seen from **Fig. 9(a)** and **(b)** that the LHS prototype is fully charged/discharged at 150/160 min.

Energy storage/discharge rate

Fig. 10(a) and **(b)** illustrates the energy storage/discharge rate of the LHS prototype during the charging/discharging process. When the HTF at 162/122°C is passed through the tubes, heat transfer takes place between the HTF and PCM. Initially, heat gets stored/discharged in the form of sensible heat only. Once the PCM reaches near the phase change temperature (142°C), heat gets stored/discharged in the form of latent heat. Similarly, after phase change of PCM, heat is stored/discharged in the form of sensible heat. When the PCM reaches an average temperature of 161°C in 150 min during the charging process, the amount of sensible, latent and total energy stored in the LHS prototype is 6.94 MJ, 10 MJ, and 16.94 MJ. The range of temperature in which the PCM stores the sensible heat is about 39°C (122–161°C). Similarly, when the PCM reaches an average temperature of 132.3°C in 165 min during the discharging process, the amount of sensible, latent and total energy discharged from the LHS prototype is 5.29 MJ, 10 MJ, and 15.29 MJ. The range of temperature in which the PCM discharges the sensible heat is about 29.7°C (162–132.3°C).

Lab Scale Prototype – Experimental Setup and Performance Evaluation

For any numerical model developed, validation with the real-time experimental data is vital for the practical applicability and further refinement of the model. In this section, details pertaining to the development of a shell-and-tube type lab-scale LHS prototype of 10 MJ capacity with multiple embedded HTF tubes and the corresponding experimental results are presented.

Experimental Setup

The schematic of the experimental setup employed for testing the thermal storage characteristics of the LHS prototype is shown in **Fig. 11**. The experimental setup consists of an oil storage tank, a high-temperature thermic fluid pump, a thermic fluid electric heater, LHS prototype, an expansion tank, a cooling tank, a positive displacement flow meter of the oval gear type, K-type metal-sheathed thermocouples and a data acquisition system. The oil storage tank having a 1000-liter capacity is utilized for storing the HTF. The huge storage capacity of the storage tank is mainly intended for storing the bulk heat, which aids in feeding a nearly constant temperature HTF to the LHS prototype. The HTF is circulated in the experimental loop by a high-temperature thermic fluid pump of single-stage centrifugal and horizontal end suction type. The pump provides enough pressure (about 2 bar) to overcome the pressure drop across the thermic fluid heater/cooling tank, LHS prototype and pipeline. A variable speed drive (frequency controller) is connected to the pump to achieve different flow velocities. The HTF is heated to the required operating temperature using the thermic fluid heater during the charging process.

The heater is of electrical resistance type and has a heating capacity of 72 kW. The electrical load supply to the heater is tuned by a controller, based on the temperature difference between the desired HTF temperature and the heater-exit HTF temperature. The oil volume is generally increased while heating due to the thermal expansion and the excess space needed to accommodate the oil is given by the expansion tank. In addition, the expansion tank serves as a deaerator, i.e., any gases if present in the thermic oil are deaerated. The cooling tank used in the setup is a water based coil-type heat exchanger. The heat exchanger coils are fabricated with

Fig. 9 Average melt fraction contours of the LHS model (a) charging and (b) discharging. Reproduced from Niyas, H., Prasad, S., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Numerical results. *Energy Conversion and Management* 135, 188–206.

flexible copper tubes. Water in the cooling tank (about 750 L) serves as the cooling medium, and the temperature of the water is maintained at near room temperature through fresh supply of water. The HTF flows through the copper tubes during the discharging process, and it is cooled down due to the heat transfer between the HTF and water. Single ported, Tee type globe valves (G1–G11) are used to change and divert the flow of HTF during charging and discharging processes. A strainer of Y-type is kept between the expansion tank and storage tank, to filter the circulating HTF from foreign particles. Non-return valves of clapper type are used at certain locations of the fluid line, *viz.* inlet and outlet of the thermic fluid heater and outlet of the storage prototype, to prevent backflow of the HTF. The LHS prototype, oil storage tank and the pipeline are insulated using glass wool of 50 mm thickness for avoiding heat loss to the ambient. The pictorial view of the experimental setup is presented in Fig. 12. During the experiment, temperature of the LHS prototype at various locations, HTF inlet and outlet temperatures and HTF flow rate are measured at a constant time interval of 5 s. A positive displacement flow meter of the oval gear type having an accuracy of $\pm 0.2\%$ is used to measure the HTF flow rate in the circuit. Nine K-type thermocouples having an accuracy of $\pm 0.2^\circ\text{C}$ are fitted to the LHS prototype to measure the temperature. LHS prototype consists of three cartridges for keeping the PCM. In the middle of the three cartridges (0.135 m, 0.435 m, 0.735 m from any side of the prototype), thermocouples are placed at three different locations, *viz.*

Fig. 10 Energy storage/discharge rate of the shell-and-tube LHS model (a) charging and (b) discharging. Reproduced from Niyas, H., Prasad, S., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype-Numerical results. *Energy Conversion and Management* 135, 188–207.

top, middle and bottom to capture the temperature variations. Details of the thermocouple locations are given in Fig. 5(a). Two K-type thermocouples are fixed, each at the inlet and the outlet of the LHS prototype for measuring the HTF temperature. The thermocouples and the flow meter are connected to a data acquisition system, which in-turn is integrated with a computer for recording the temperature and the flow rate data. The data acquisition system consists of Agilent 34972A data logger (having a precision of $\pm 0.1^\circ\text{C}$) and Agilent 34901A 20-channel multiplexer.

Latent Heat Storage Prototype

The schematic of the LHS prototype employed for testing the storage characteristics is shown in Fig. 13. A ternary mixture comprising of potassium nitrate, sodium nitrate and sodium nitrite in the weight proportion of 53:7:40 is selected as the PCM. In the current study, the temperature difference between the initial temperature of PCM and the inlet temperature of HTF is fixed as 40°C . As the selected PCM has a melting point of 142°C , the initial temperature of PCM and the inlet temperature of HTF during charging/discharging process are taken as $122/162^\circ\text{C}$ and $162/122^\circ\text{C}$, thereby making a temperature swing of 20°C on both sides of the melting point. The outer diameter (d) and thickness of HTF tubes are 12.7 mm and 2 mm. The height (h) and thickness (b) of the longitudinal fins attached to the tubes are 10 mm and 1 mm. The number of HTF tubes (N_T) and fins (N_F) on each tube in the optimized LHS prototype are 25 and 4. The HTF tubes and fins are made of copper. The outer shell of the prototype is made of stainless steel (SS304) of diameter 335 mm OD and 5 mm thickness. The physical LHS prototype with insulation and temperature sensors is given in Fig. 14.

Experimental Procedure

The entire experimental procedure can be subdivided into four processes, which should be carried out in sequence.

Preheating the oil – Storage prototype bypass

The HTF should be heated up to the desired HTF inlet temperature of the charging process. For achieving this, a bypass line is provided in the experimental loop so that the HTF re-circulates without entering the LHS prototype. Valves G3, G6, G8 and G9 are closed during this process. Once the HTF reaches the desired inlet temperature for charging process, this process is said to be completed.

- 1 – Oil storage tank 2 – Thermic fluid pump 3 – Thermic fluid electric heater
 4 – LHS prototype 5 – Oval gear flow meter 6 – Expansion tank 7 – Cooling tank

Charging

When HTF reaches the desired inlet temperature for charging process, the HTF is passed through the LHS prototype to initiate the charging process. Valves G4, G6, G9 and G10 are closed during this process. The process continues until the prototype is fully charged.

Cooling the oil – Storage prototype bypass

Once the LHS prototype is fully charged, the HTF is then cooled down to the desired HTF inlet temperature for the discharging process. The HTF is made to flow through the cooling tank for achieving the same. Valves G3, G5 and G7 are closed during this process. Once the HTF reaches the desired inlet temperature for the discharging process, this process is said to be completed.

Discharging

When HTF reaches the desired inlet temperature for the discharging process, the HTF is allowed to pass through the prototype and thereby discharging of LHS prototype gets started. Valves G3, G5 and G6 are closed during this process. The process continues until the prototype is fully discharged.

Results and Discussions

In the following sub-sections, various results obtained during the performance testing of the lab-scale LHS prototype during the charging and discharging processes are presented. The major implications of the results are also discussed. The initial average temperature of the LHS prototype during the charging/discharging process is 122/162°C and a comparatively higher/lower temperature HTF at 162/122°C is allowed to pass through the HTF tubes.

Temperature variation

Fig. 15(a) and **(b)** illustrates the local temperature variation of the LHS prototype during the charging and discharging processes. When the high/low temperature HTF is passed through the HTF tubes during the charging/discharging process, heat transfer takes between the high/low temperature HTF and the comparatively low/high temperature PCM through the HTF tubes. It can be noted from **Fig. 15(a)** and **(b)** that the increase/decrease of temperature is faster in cartridge 1 than cartridges 2 and 3 during the charging/discharging process. A similar trend is observed between cartridge 2 and 3. This is due to the fact that there exists a higher heat transfer potential due to more temperature difference in the entry portion than the exit portion of the prototype. It can be seen from **Fig. 15(a)** that the increase in temperature of the PCM in the top region of the prototype is faster than that of middle and bottom regions in all the cartridges. This is due to the buoyancy driven natural convection wherein the high temperature and less dense particles move to the top portion of the prototype. It can be noted from **Fig. 15(b)** that the PCM temperature in the bottom portion decreases slightly faster than the middle and top portions. This is due to the negligible natural convection that exists during the solidification process. In addition, it can be inferred from **Fig. 15(a)** that there is a steady increase in temperature up to a certain point, after that the slope of the curve decreases and finally after a certain interval, the temperature has increased sharply. This transition is due to the melting phenomenon during which a large amount of latent heat gets stored in the PCM. However, a similar trend is not noticeable in the temperature values of the top portion of all cartridges. This is due to the convective

Fig. 15 Local temperature variation of the lab-scale LHS prototype during (a) charging and (b) discharging. Reproduced from Niyas, H., Rao, C.R.C., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Experimental results. *Solar Energy* 155, 971–984.

movement of the higher temperature particles in the top portion, by which the temperature has increased sharply. Due to the conduction heat transfer that takes place in the PCM throughout the solidification process, there exists an even temperature distribution in the radial direction of the prototype. Unlike charging process, a sharp plateau is not noticeable in the discharging process. This is because the heat source input during the discharging process is the LHS prototype itself, the potential of which is reduced while exchanging heat with the HTF. In addition, during the discharging process, a thin solid layer of PCM is formed around the HTF tube. Over a period, the thin layer becomes thicker. This increases the thermal resistance and hence, the solidification rate reduces. The uncertainty in the temperature measurements is about $\pm 0.2^\circ\text{C}$. The average temperature of PCM during the charging process is about 160.6°C in 150 min, which is 1.4°C less than the HTF inlet temperature. Similarly, the average temperature of PCM during the discharging process is about 131.6°C in 165 min.

Charging/discharging time

Fig. 16(a) and **(b)** depicts the local melt fraction variations of the LHS prototype during the charging and discharging processes. The local melt fraction is calculated based on the temperature of the PCM (recorded at nine different locations) using the Eq. (10). It is seen from **Fig. 16(a)** that the top portion of the cartridges have a steady increase in melt fraction when compared with the bottom cartridge. This is due to the convection heat transfer occurred during the melting of PCM, wherein the molten PCM moves from the bottom to the top portion of the prototype. On the contrary, it is seen from **Fig. 16(b)** that the top, middle and bottom portion of the cartridges have a steady decrease in melt fraction evenly. This is due to the uniform conduction heat transfer in the PCM. In addition, it can be seen from the above results that PCM in the 1st cartridge has melted/solidified faster than 2nd and 3rd cartridges and similar tendency is observed between 2nd and 3rd cartridges. This is due to the higher heat transfer potential available at the entrance of the LHS prototype than the exit of the prototype. The uncertainty involved in the estimation of melt fraction is about ± 0.061 . It took about 123 min for the LHS prototype to reach an average melt fraction of unity. Similarly, it took about 131 min for the LHS prototype to reach an average melt fraction of zero.

Energy storage/discharge rate

Fig. 17(a) and **(b)** illustrates the energy (sensible, latent and total) storage and discharge rate of the LHS prototype during the charging and discharging processes. Sensible, latent and total heat stored/discharged in/from the PCM are calculated using the

Fig. 16 Local melt fraction variation of the lab-scale LHS prototype during (a) charging and (b) discharging. Reproduced from Niyas, H., Rao, C.R. C., Muthukumar, P., 2017. Performance investigation of a lab-scale latent heat storage prototype – Experimental results. *Solar Energy* 155, 971–984.

Eqs. (11)–(16), respectively. During charging, when the high-temperature HTF at 162°C is passed through the tubes, heat from the HTF is transferred and stored in the PCM. Similarly, during discharging, when the low-temperature HTF is allowed to pass through the HTF tubes, the stored heat from the PCM is discharged to the HTF.

Initially, when the PCM is in the solid/liquid state during charging/discharging, heat gets stored/discharged in the form of sensible heat only. Once the PCM reaches near the phase change temperature (142°C), heat gets stored/discharged in the form of latent heat. Similarly, after melting/solidification of the PCM, heat is stored/discharged in the form of sensible heat. During charging, when the PCM reaches an average temperature of 160.6°C in 150 min, the amount of sensible, latent and total energy stored in the LHS prototype are 6.87 MJ, 10 MJ and 16.87 MJ, respectively. The range of temperature in which the PCM stores the sensible heat is about 38.6°C (122 – 160.6°C). During discharging, when the PCM reaches an average temperature of 131.6°C in 165 min, the amount of sensible, latent and total energy discharged from the LHS prototype are 5.41 MJ, 10 MJ and 15.41 MJ, respectively. The range of temperature in which the PCM discharges the sensible heat is about 30.4°C (162 – 131.6°C). It can also be noted from Fig. 17(a) and (b) that the sensible and latent energy storage/discharge rate curve has a similar trend like average temperature and melt fraction curve. Because, the sensible and latent energy stored/discharged depends only on the average temperature and the average melt fraction of the PCM.

Development of Industrial Scale LHS System

With the expertise and knowledge gained from the experimental and numerical investigations, the studies have been extended to develop an industrial-scale LHS system of 0.25 GJ capacity. The developed LHS module is then integrated with a commercial steam accumulator storage system of 1 GJ storage capacity. This combined storage system has been installed in the LFR based pilot-CSP plant in Vallipuram, Tamil Nadu, India.

Pilot CSP Plant With TES

Fig. 18 shows the pictorial view of the 50-kWth LFR solar collector field with TES system, located in Vallipuram, Tamil Nadu, India. The steam accumulator will maintain the continuous supply of steam when the demand of the power plant is higher than the

Performance investigation of a lab-scale latent heat storage prototype – Experimental results. *Solar Energy* 155, 971–984.

Fig. 18 LFR solar collector field with TES.

supply. It also supplies the required amount of steam during the start of the plant. For storing 1 GJ of steam at 55 bar and 270°C, the required volume of steam accumulator has been found to be 16 m³. An industrial-scale LHS module of 0.25 GJ storage having four cartridges of PCM (each of 62.5 MJ capacity with 0.125 m³ volume) in the form of shell-and-tube type heat exchanger has been integrated with the steam accumulator for extended supply of steam and also to compensate the decline in the steam temperature during consumption. The steam accumulator integrated with PCM module is installed between the evaporator and super heater solar field modules. **Fig. 19** shows the schematic layout of the 50-kWth solar collector field with TES system. The steam entering the PCM module gets condensed by supplying its energy to the PCM and the saturated liquid is fed to the

Fig. 19 Layout of solar collector field with TES.

Table 7 Specifications of the steam accumulator

Thermal energy storage capacity	1 GJ
Pressure vessel internal volume	16 m ³
Material of construction	Carbon steel SA516 Gr 70
Maximum allowable working pressure	60 kg/cm ²
Maximum allowable working temperature	280°C
Design (metal) temperature	380°C
Hydrostatic test pressure	90 kg/cm ²
Charging pressure	55 kg/cm ²
Discharging pressure	45 kg/cm ²
Charging maximum steam flow rate	800 kg/h
Discharge steam flow rate	500 kg/h
Total weight	17,500 kg

accumulator unit. During discharging the saturated liquid circulates through the PCM module and generates steam. The selected PCM is a mixture of sodium nitrate (60 wt.%) and potassium nitrate (40 wt.%). The PCM melts at 222°C, stores 0.25 GJ of energy and releases the same amount of energy during solidification when the temperature of the system reduces below 222°C. The PCM containments and fittings occupy about 0.5 m³.

Steam Accumulator

Steam accumulator is an insulated steel pressure vessel containing saturated water and saturated steam under pressure. It is one of the commonly used thermal energy storage devices. It is used to smooth out peaks and troughs in demand for steam. The key purpose of the steam accumulator is to release steam when the demand is greater than the solar boiler's ability to supply at that time, and to accept steam when demand is low. The steam accumulator can be integrated with the steam generating system either in series or in parallel configuration. In our case, series configuration is used. The technical specifications of the steam accumulator are given in [Table 7](#). The steam accumulator installed at the project site is shown in [Fig. 20](#).

Industrial-Scale LHS Module

[Fig. 21](#) depicts the pictorial representation of the CAD and actual industrial-scale LHS module. The industrial-scale LHS module is of square shape (63 × 63 cm) and is segmented into four cartridges of length 50 cm each, which makes the overall length of the

Fig. 20 Steam accumulator.

Fig. 21 Industrial-scale PCM module (a) CAD model and (b) actual module.

module to be 2 m. About 121 HTF tubes are arranged in an 11×11 array through which the pressurized water will flow thereby exchanging the heat with the PCM. In general, majority of the PCMs are highly corrosive in nature. Hence, entire LHS module is made up of stainless steel to prevent corrosion. The partition between the cartridges is made of concrete poured between the two plates both of which are machined using laser cutting process. The main advantage of this method is that it ensures a leak proof partition between the PCM cartridges. The inlet and outlet supply of HTF is accomplished by using a header assembly. Six K-type thermocouples are inserted in each cartridge to capture the temperature of the PCM. The specifications of the LHS module and materials used are given in [Tables 8](#) and [9](#).

Binary PCM Mixture Preparation and Filling Process

Preparation of a binary mixture from two salts having different melting points is a challenging task. The main strategy in the preparation of the binary mixture is to melt the PCM having lower melting point first. Then add the other PCM to the mixture thus

formed and continuously heating slightly above the melting point of the PCM having the higher melting point. **Fig. 22** shows the pictorial view of the melting and filling of PCM in the LHS module. It was found that the total weight of the PCM required per cartridge is about 302 kg (181 kg of sodium nitrate + 121 kg of potassium nitrate). The following steps have been followed to prepare the binary PCM mixture.

- Initially it was made sure that the mixing vessel was clean.
- The mixing vessel was placed on the support stand with burner underneath.
- Then the entire setup was placed on the weighing machine, this weight was set as tare weight.
- Sodium nitrate was added to the mixing vessel and was heated up to its melting point (306°C).
- It was ensured that the weight of sodium nitrate was about 181 kg after moisture removal.
- Soon after melting sodium nitrate, 121 kg of potassium nitrate salt was added.
- Salt mixture was continuously heated till 334°C (melting point of potassium nitrate).
- The mixture was continuously stirred during the melting process.
- After moisture removal of the salt mixture, the weight of the mixture was ensured for 302 kg and the final weight compensation was done with KNO₃ salt.

- The salt mixture was heated up to 350°C and it was maintained for 6 h.
- The molten salt was drained into one cartridge of the industrial-scale LHS module.
- The same process was repeated for the remaining 3 compartments.

Conclusions

This work presents a detailed study on the various stages involved in development of an industrial-scale latent heat storage (LHS) system. Preliminary studies are conducted in a lab-scale LHS prototype of 10 MJ storage capacity. A ternary salt mixture comprising of potassium nitrate, sodium nitrate and sodium nitrite in the weight proportion of 53:7:40 is used as the phase change material (PCM) in the lab-scale LHS prototype. Hi-Tech Therm 60 is used as the heat transfer fluid (HTF). Performance parameters viz., melt fraction, charging/discharging time and energy storage/discharge rate were evaluated at different operating conditions. It is found from the experimental and numerical studies that the effect of natural convection is very much predominant during the charging process, whereas its effect is negligible during the discharging process. With the expertise and knowledge gained from the experimental and numerical investigations, the studies have been extended to develop an industrial-scale LHS system of 0.25 GJ capacity. A binary salt mixture comprising of sodium and potassium nitrate in the weight proportion of 60:40 is used as the PCM in the industrial-scale LHS module. The developed LHS module is then integrated with a commercial steam accumulator storage system of 1 GJ storage capacity. This combined storage system has been installed in the LFR based pilot-CSP plant in Vallipuram, Tamil Nadu, India. The current study will be helpful in developing large-scale LHS systems for real-time CSP plants.

Nomenclature

ARF Advanced recycling fees is the cost of recycling the product procured by the producer from the consumer during retail selling.

EEE Electrical or electronic equipment utilised by consumers in a market.

EOL End of life is a term denoting the final stage of a product life cycle in the market.

EPR Extended producer responsibility is a strategy designed to promote the integration of environmental costs

associated throughout a products' life cycles into the market price of the products.

E-waste Waste generated by discarding electrical or electronic equipment by a consumer.

MEIS It is a scheme brought by the Government of India to provide incentive for exporting Indian manufactured goods in the world market.

Introduction

The Problem

The problem of recovering metallic materials from e-waste can be best described from the following two comments. "Never mind that it is also an economic stupidity because we are throwing away an enormous amount of raw materials that are essentially re-useable," said Mr. Achim Steiner, Executive Director of the UN Environment Programme (UNEP). "Whether it is gold, silver or some of the rare earths that you have heard about perhaps in recent years, it is still an incredible amount." The emphasis is on the electronic waste, for the current article, which is inexorably rising with time in our contemporary world as subtle consequence of the advent of digitalization. A broader glimpse of the global outline such waste generation can be perceived by the following schematic (Fig. 1).

It is ironic that the boom in advance electronic and electrical technology should bring in its wake a looming danger from the growing pile of electronic waste. The world community, through several authorized bodies, now recognizes that it is necessary to address the dual concerns of recovery of valuable metals from e-waste as well as safe disposal of the hazardous in e-waste. The threat perception by national and international bodies has heightened recently, as the enormity of the problem becomes more clear, aggravated by the accelerated usage of electronic items in the developing countries in Asia powered by improvements in national economy.

The global quantity of e-waste generation in 2014 was found to be around 42 Mt (Million Tons) as reported by the United Nations (see "Relevant Websites section"). To give an idea, a number of 1.15 million trucks with 40-ton (18-wheel) capacity will be completely filled with the e-waste generated in the world, enough to form a line covering 23,000 km, twice the distance between New York and Tokyo. Approximately, 4 billion people in the world are covered by national e-waste legislation, though legislation does not necessarily come together with enforcement. By these national laws, only around 6.5 Mt (16%) of this plethora of e-waste was reported as formally treated by national collection systems. For example, in total, 0.7 Mt of e-waste was thrown into the waste bin by the 28 EU Member States. The amount of e-waste that is disposed of in waste bins is unknown for other regions. The quantities of the collection outside formal take-back systems are not documented systematically. However, they are likely to be a hiatus between e-waste generated, e-waste officially collected and e-waste in the waste bin.

The latest reported accounts of e-waste generation, comprised of 1.0 Mt lamps, 3.0 Mt of Small IT products such mobile phones, calculators etc., 6.3 Mt of screens and monitors, 7 Mt of temperature exchange equipment (cooling as well as freezing), 11.8 Mt large equipment, and 12.8 Mt of small equipment. This amount of e-waste is expected to grow to 49.8 Mt in 2018, with an annual growth rate of 4%–5% (Baldé *et al.*, 2015) (Refer Fig. 2).

To cite an example of e-waste recovery, Teck, a Canadian based company at Trail, British Columbia, became the first metal supplier in Olympic history to include metals recovered from e-waste in the Olympic medals. It developed an e-waste recycling process which maximizes metal recovery, operating its own smelter and refinery. Metals were recovered from cathode ray tube (CRT) glasses, computer parts and circuit boards through separation, segregation and smelting. Over a 77,000 tonnes of e-waste acquired have been processed in between 2006 and 2015 (Mining & Metals in a Sustainable World, 2050, 2015). E-waste constitutes a reliable and rapidly increasing source of metals ensuring the long-term sustainability of Teck's operations. Moreover, the use of e-waste as a source of scrap enables the saving of energy that would have otherwise been used to generate mined resources. For instance, from e-wastes collected in Japan, the "mine" of gold and silver contained in small consumer electronics is equivalent to 16% and 22% of the world's total reserves, respectively. With an eye towards a sustainable future, the 2020 Olympic host has decided to make the medals by tapping the urban mine rather than asking the mining companies for donation (see "Relevant Websites section"), see Figs. 3–5.

Fig. 1 A global scenario: E-waste generation, 2014. Reproduced from Honda, S., Khetriwal, D.S., Kuehr, R., 2016. Regional E-Waste Monitor: East and Southeast Asia. Bonn, Germany: United Nations University, ViE- SCYLE.

Global Estimated e-waste production

Fig. 2 Global production of e-wastes per year. Reproduced from Baldé, C.P., Wang, F., Kuehr, R., Huisman, J., 2015. The Global E-Waste Monitor – 2014". Bonn, Germany: United Nations University, IAS – SCYCLE.

The above estimation from the monetary evaluation of extractable precious and semi-precious metals does seem lucrative but the bitter truth is that only a fraction of this amount is extracted in the present world scenario. It is just not the economics, but also the potential of mankind to extract using productive technologies without harming the ecological balance. From the resource

Fig. 3 Economic evaluation of e-waste. Reproduced from Baldé, C.P., Wang, F., Kuehr, R., Huisman, J., 2015. The Global E-Waste Monitor – 2014". Bonn, Germany: United Nations University, IAS – SCYCLE.

Fig. 4 Connections made from gold or silver in the cell phone circuit boards discarded as e-waste (<http://www.bbc.com/news/business-37163074>).

perspective, e-waste is a potential “urban mine” which can provide a great amount of secondary resources for remanufacture, refurbishment and recycling of a lot of metals which are very precious, uneconomic in mine extraction and also rare. For instance, the gold content from e-waste generated in the year of 2014 was roughly 300 tonnes, which represents 11% of the global gold production from mines in 2013 (2270 tonnes), reported by the U.S Geological Survey (George, 2014).

Recovery of such valuable materials requires both high collection rate and recycling efficiency. In order to exploit the opportunities, appropriate policies are imperative to facilitate the creation of an infrastructure and ensure that all accumulated e-waste is treated using the state-of-the-art technologies.

Definition

Information and communication technologies; consumer electronics including toys; large household equipment, such as dishwashers and washing machines; medical equipment; and electric tools have become central to our daily lives. People are enjoying

what technology provides, surfing the Internet, buying daily merchandise on their smart phones or tablets and watching high-definition movies on their televisions at home. As more and more electronic products are produced to satisfy the demands worldwide, more resources are used to produce these items. Hence, a rapid growth of computing and communication equipment is driving the ever-increasing production of electronic waste (e-waste). As observed by the United Nations, there is a presence of a global inconsistency in the understanding and application of the term “e-waste” in both legislation and everyday use. This had repercussions in the form of many definitions contained within e-waste regulations, policies and guidelines. The term “e-waste” itself is self-explanatory, in the sense that it is an abbreviation of “electronic waste”. A key part of the definition is the word “waste” and what it logically implies – that the item has no further use and is rejected as useless or excess to the owner in its current condition.

“E-waste is a term used to cover items of all of electrical and electronic equipment (EEE) and its parts that have been discarded by the owner as waste without the invention of re-use” (One Global Definition of E-waste, 2014).

The act of discarding an EEE as e-waste is considered when the owner decides the item is no longer useful to them due to any kind of failure, technical capability, cosmetic condition, age, replacement, organizational policy, depreciation, etc. The word “discard” is defined in the Merriam Webster dictionary as “to throw (something) away because it is useless or unwanted”, and in the Cambridge Dictionary as “to throw something away or get rid of it because you no longer want or need it”. There are none requisites for the equipment to be non-functional, to be designated as e-waste by the owner, as it is solely the owner’s discretion, if they so decide.

Constituents of E-Waste

From the point of view of material composition, electronic waste can be defined as a mixture of various metals, particularly copper, aluminium, and steel, attached to, covered with, or mixed with various types of plastics and ceramics (Table 1). Precious and semi-precious metals have a variety of applications in the manufacture of electronic equipment, as contact materials due to their high chemical stability along with good conductivity. The more the electric charge transfer, more is the required nobility of the material, and so is the price. Gold plated contacts in earphone jacks, integrated circuit connectors in smart phones etc., are some examples. Platinum group metals, are used more among other inert metals in integrated circuits (Platinum silicide Ohmic

Cui, J., Zhang, L., 2008. Metallurgical recovery of metals from electronic waste: A review. *Journal of Hazardous Materials* 158, 228–256.

and Schottky contacts), Displays, sensors (MOSFET's, thermocouples), etc., as they are the high temperature coefficient or long term stability (Seymour and Davey, 1985).

Table 2 gives chemical analysis of the metallic metals present in various e-waste divided into two categories; common metals and precious metals. Steel is the most common alloy used for fabrication, signifying the presence of Iron, such as in mobile phone casings, DVD player, PC casings etc., refer **Table 2**. Copper, another most common metal, is extensively used in circuit wires, and substitute for a high conductivity material in the EEE's. It is quite important to recover, copper as much as possible, in the context of augmented demand of copper and dwindling reserves. In few decades, known deposits of copper ores may get completely exploited at the current rate of copper consumption which may lead to a crisis of this crucial metal. Moreover, Nickel similar to Copper is also widely utilised in circuit constructions, batteries (Ni-Cd batteries), and fuel cells, also in various nanoscale application (see "Relevant Websites section"). Aluminium is another metal which is generally found in integrated circuit designed components such as laptops, PCs, smartphone casings etc. Aluminium recovery is of great importance; an analogy can be made by the fact that around 47% of the entire Aluminium in the EU market is obtained from recycling Aluminium components. Aluminium recovery from e-waste shall play a great significance in its global industry. Additionally, other than precious metals like gold, silver and platinum, the presence of semi-precious metals in e-waste such as gallium (Ga), palladium (Pd), tantalum (Ta), tellurium (Te), germanium (Ge) and selenium (Se) makes it attractive for recycling and recovery. E-waste is considered hazardous if the elements like mercury, lead, arsenic, cadmium, selenium, hexavalent chromium and some flame retardants are present beyond permissible amounts.

Disposal of E-Waste

Waste electric and electronic equipment (WEEE); another term which is common for e-waste, has been taken into consideration due to the hazardous material contents of e-waste. Currently, the main options for the treatment of electronic waste are involved in reuse, remanufacturing, and recycling, as well as incineration and landfills. Reuse of end of-life (EOL) electronic equipment is the primary priority in management of electronic waste since the performance life of equipment is extended on a secondary market, resulting in a reduction of actual treatable e-waste. Remanufacturing is a production-batch process where this concept is applied. Used products or cores, are disassembled, cleaned, repaired or refurbished, reassembled and retested to manufacture the original or a similar type of the equipment (Williams and Shu, 2001). Alternatively, recycling is the reprocessing in a production line of the waste materials for the original or other applications. Recovery of the metals are the upshot of this recycling process of e-waste (One Global Definition of E-waste, 2014) (**Fig. 6**).

Hazardous and Toxic Constituents of E-Waste

E-waste is a source of useful as well as toxic materials. Circuit boards and other components can contain arsenic, cadmium, mercury, lead flame retardants containing halide substances etc., some of which become biologically active (Mihai, 2016). These hazardous materials are potential serious environmental and health threat. If burnt, some materials release toxic halogen gases, dioxins and furane. An alarming aspect of such hazardous waste from US and Europe to Asian and African countries, which have been exposed by the Basel Action Network (BAN) a non-governmental watchdog body on disposal of e-waste.

Fig. 6 Steps taken after remanufacturing. Reproduced from Honda, S., Khetriwal, D.S., Kuehr, R., 2016. Regional E-Waste Monitor: East and Southeast Asia. Bonn, Germany: United Nations University, ViE- SCYLE.

Table 3 The terms vis-à-vis steps performed from EEE to E-waste

Step	Description
Manufacture	The phase of the EEE product lifecycle where it is manufactured
Use	First phase of application of the EEE product in its service life
Discard	The decision by the owner to discard or not discard the product. Discarding indicates it becomes e-waste, whereas not discarding and routing to reuse indicates it is not waste. (cf. 1.1)
Reuse	Reuse of electrical and electronic equipment or its components is to continue the use of it (for the same purpose for which it was conceived) Products could be donated or traded before or during this phase (One Global Understanding of Re-Use, Common Definitions, 2009)
Preparation for Reuse	Preparation for reuse comprises any operation performed to bring used EEE or its components into a condition to meet the requirements of a next potential owner (secondary market) (One Global Understanding of Re-Use, Common Definitions, 2009)
Recycle	The phase of the product lifecycle where due to lack of usability, cosmetic condition or age the product is broken down into component materials and recycled to raw materials for the manufacture of new EEE or other products (Recommendations, 2014)
Disposal	Material which cannot be recycled into raw material for further use, would need to be disposed, using methods, such as energy recovery or landfilling. Items that are disposed of in household bins may move directly to this phase avoiding any opportunity of reuse or recycling

One Global Definition of E-Waste, 2014. Solving the E-Waste Problem (Step). Bonn: White Paper, pp. 4–5. ISSN: 2071-3576.

Just “by discarding” an electronic component on personal whims and fancies may have a serious impact when integrated. The e-waste is finally dumped if not recycled, into landfills. Along the passage of time, metallic ions or atoms diffuse to the ground water or gets channelled to water bodies, severely affecting the eco-system and its inhabitants. For example, Lead and Mercury are highly potent neurotoxins, particularly among children, who can suffer from Intelligent Quotient (IQ) deficiency and growth abnormalities even at very low levels of exposure. Cadmium, a toxic metal found in circuit board, is listed by the Environmental Protection Agency (EPA), as a “probable human carcinogen”, and also produces pulmonary damage when burned and inhaled ([Mundada et al., 2004](#)). The environmental issues related with e-waste are aggravated due to the low collection rates of e-waste containing hazardous components as the final owner either hides the equipment in his own house or disposes those via normal unmarked bins, ending up at landfills or incineration setups. Another possibility which is becoming more and more common currently, is where the waste materials reaches developing countries where the treatment processes may not follow the standard practice. For instance, nearly 40% of EEE waste generated in the US lands in developing Asian countries. Nearly all of these exports were illegal under US law. Scale of e-waste exported to Asia has previously been difficult to estimate. According to Jim Puckett, coordinator, BAN, GPS trackers were used inside old printers and monitors sent to recycling centres in the US to enable them to get a clearer picture.

It is true that North America and Europe generate vastly more e-waste per capita than Asia or Africa. Sustainability activists have for years urged the developed world to stop dumping e-waste loaded with heavy metals and toxins in countries like Nigeria or Ghana (see “Relevant Websites section”). The change occurred to the signing of Basel Convention, where these African countries have curbed their e-waste imports. Ideally, optimum efficiency and low environment impacts can be achieved when the e-waste is properly collected and is in the state of art facilities within the boundaries of the same country. Imperfect disposal techniques still prevail, causing e-waste problems.

The EEE goes through a set of stages which are elucidated ([Table 3](#)) using the following flow diagram ([Fig. 7](#)). These are the steps undertaken after an equipment is discarded at the user’s discretion ([Fig. 8](#)).

Fig. 7 E-waste pile at a recycling plant at Hubei, China (<https://www.nature.com/news/take-responsibility-for-electronic-waste-disposal-1.20345>).

E-Waste Scenarios: Different Landmasses of Our Planet

Asian and Oceanic Countries

China

The top three Asian countries with the highest e-waste generation in absolute quantities are China (6.0 Mt), Japan (2.2 Mt) and India (1.7 Mt). The top three Asian regions or countries having the highest e-waste generation in relative quantities are: Hong Kong (21.5 kg/inh.), Singapore (19.6 kg/inh.) and Brunei (18.1 kg/inh.). A record 16 Million tons of electronic trash, containing both toxic and valuable materials, was generated in 2014, in Southeast Asia. The generation rate soared up by 63% in just five years (Baldé *et al.*, 2015). Due to rapid advancement, the average lifespan of computer has shrunk to less than two years. "Growing incomes, the creation of more and more gadgets and ever-shorter life spans of things like mobile phones are the reasons for this tremendous increase in Asia," said, Ruediger Kuehr, Head of the United Nations University Institute for Sustainability and Peace SCYCLE (Figs. 9 and 10).

In China the mountain of discarded TVs, phones, computers, monitors, e-toys and small appliances grew by 6.7 m tons in 2015 alone, i.e., a 107% increase when compared to that of 2010 data. For an analogy, if every woman, man and child in China had an

Fig. 9 EEE to E-waste, outcomes of discarding components. Reproduced from One Global Definition of E-Waste, 2014. Solving the E-waste problem (step). Bonn: White Paper, pp. 4–5. ISSN: 2071-3576.

Fig. 10 E-waste distribution over Asian countries (in Kg/inhabitants). Reproduced from Baldé, C.P., Wang, F., Kuehr, R., Huisman, J., 2015. The Global E-Waste Monitor – 2014”. Bonn, Germany: United Nations University, IAS – SCYCLE.

old LCD monitor and accumulated in a pile, it would not equal the 2015 tonnage. Yet, Asia's 3.7 kg per person of waste is still a writ compared to Europe's 15.6 kg per person (see "Relevant Websites section").

Most collection activities in China are carried out in urban areas due to high population density and the availability of large volumes of e-waste. Informal workers perform door-to-door collection and serve as an interface between consumers and medium level scrap dealers, renovators and recyclers. Around 440,000 people are involved in informal e-waste collection. After collection, this e-waste is sorted and usable appliances and valuable components are sold to the second-hand market. Guiyu, which is the largest e-waste recycling site in China and the world, recycles about 1.5 Mt per year, has a population of 150,000 people, nearly 100,000 of whom are migrant labourers engaged in recycling operations. In these informal recycling hubs, the treatment of WEEE is mainly carried out via primitive methods, such as hammering, manual sorting, open burning and acid leaching (Yu *et al.*, 2010; Honda *et al.*, 2016). Apart from domestic generation of e-waste, China remains one of the largest recipients of e-waste from other countries. Despite the fact that Chinese government having banned the import of e-waste (for both domestic reuse and recycling) in 2000 and having ratified both the Basel Convention in 1991 and BAN Amendment in 2001. Scrap dealers and smugglers now use less direct and visible means to import e-waste into China. China has trailed a unique scheme to improve its e-waste recycling system. Given the widespread existence of informal e-waste collectors and recyclers, formal recyclers have difficulty accessing e-waste products, as they are unable to compete on price given higher treatment costs in the formal sector. Consequently, to promote more environmentally sound recycling system, the Chinese government has several policies that provide incentives the channelization of e-waste into the formal sector. As a result, many facilities have cropped up in recent years with additional help from investments by foreign recycling companies, often with state-of-the-art equipment for processing e-waste (Zhong and Zhao, 2012; Honda *et al.*, 2016).

South Korea

The Republic of Korea, also known as South Korea, has a population of around 49 million 27, half of which resides in the metropolitan area surrounding the capital, Seoul. The other populous urban regions include Busan, Incheon, Daegu, Daejeon and Gwangju. Almost 82 per cent of the country's population is urbanized (World urbanization Prospects, 2014). South Korea is a gadget-mad country. It had, for example, worldwide the highest overall mobile ownership of 99 per cent, with 67 per cent owning smart phones, generating slightly over 800,000 tonnes of e-waste through almost all EEE product categories (see "Relevant Websites section"). By the year 2015, the country has managed to recycle 21% of the total 0.8 million tonnes of e-waste generated. The capitol, Seoul, recycles a significant fraction of the e-waste that it produces. It has set up the "Seoul Resource Centre" which receives 20 per cent of the Seoul's generated e-waste for the recovery of valuable metals such as gold, copper, etc. The other 80% of Seoul's e-waste is used entirely for landfilling (see "Relevant Websites section") (Fig. 11).

Management of e-waste was conceptualized in Korea in 1992, with refund of T-V and Washing machine under the Producer Deposit Refund Scheme. The act on the resource circulation of electronic and electrical equipment was constituted by combine efforts from Ministry of Environment, Ministry of Knowledge economy (now Ministry of trade, industry and energy), and the Ministry of Land, Transport and Marine affairs. By law the Ministry of Environment may impose penalties on defaulters (Honda *et al.*, 2016; see "Relevant Websites section").

India

The Indian information technology (IT) industry has played a major role in driving the change in the economy in the last decade along with a significant contribution to the digital revolution, being experienced by the world. India generated about 0.2 million tons of E-waste in 2006 and in 2010 it is about 0.4 million tons (Needhidasan *et al.*, 2014). The figure has soared rapidly to about 1.7 Million Tonnes of e-waste in the year 2014. India, which has emerged as the world's second largest mobile market, is also the

fifth largest producer of e-waste, discarding roughly 18.5 lakh tonnes of electronic waste in the year 2016 which is nearly 12 percent of the global e-waste production, reveals the joint study on 'Rethinking Waste-Scaling Opportunity in India' released at the capital, New Delhi (see "Relevant Websites section").

It has been a level of concern for India in recent years due to rise in levels in e-waste generation. India has emerged as the second largest mobile market with 1.03 Billion subscribers and at the same time 5th largest producer of e-waste in the world. Annually, 18.5 lakh metric tons of e-waste has been discarded. In comparison to the year 2007, by 2020 e-waste from old mobiles and computers will rise by about 1800% and 500% respectively. According an ASSOCHAM-KPMG joint study, 1.5% of the total e-waste generated is recycled by formal recyclers and another 8% of the e-waste is rendered useless and goes to landfills (see "Relevant Websites section").

The Ministry of Environment, Forest and Climate Change rolled out the E-waste Management Rules in 2016 with the goal of reducing e-waste production and increasing recycling in the most efficient and suitable manner. By these rules, the government introduced a similar concept to that in the South-east Asian advanced countries like China, South Korea. The Extended Producers Responsibility (EPR). This makes manufactures liable to collect 30%–70% of the e-waste they produce over a period of seven years (see "Relevant Websites section").

Fig. 14 E-waste transfer from Australia to Asian countries. Reproduced from Baker, E., Bournay, E., Harayama, A., Rekeciewicz, P., 2005. Vital waste graphic. In: Proceeding of the Conference to the Parties of the Basel Convention, pp. 32–33. Arendal, Norway: GRID-Arendal, UNEP.

The policy and target of e-waste collection in Indian market needs to be reviewed with the introduction of new incentive scheme before the industries. On a urgent basis India needs an urgent recycling policy for its mountain of electronic waste. The waste is expected to reach a total of around 30 million tonnes by 2020 in India (see "Relevant Websites section"). Government of Indian has framed a draft proposal which is still under discussion and will be launched very shortly. They are showing already effective, but there is still a pressing need for national policy to alleviate damage to the environment. This will also generate employment and commercial opportunities, address health and safety concerns, and forge a path towards sustainability (see "Relevant Websites section").

Australia

Australia produces substantial amounts of e-waste in the world. In 2007–2008, 0.1 Mt tonnes of e-waste as generated, which are composed of discarded televisions, computers and their products and mobile phones and about 0.47 Million Tonnes in the

year 2014. The estimated production of e-waste in Australia by 2027–2028 will exceed 181,000 tons. The recycling of e-waste in Australia is limited. It is reported that about 10% of e-waste was recycled and 80% was disposed in landfills during 2007–2008 (see “Relevant Websites section”). Australian Bureau of Statistics reported that more than 50% of the e-waste generated in 2010 was either land filled, stored or incinerated (Pink, 2010).

Australia used to save itself by exporting e-waste to Singapore, India and indirectly China for processing (Refer Fig. 12). As per the Basel convention, it has become illegal to export e-waste overseas until the receiving country has the facility to process wastes in eco-friendly manner. Australia, complies with the Basel Convention by controlling the trans-boundary movements of hazardous wastes and their disposal. Keeping in view the strict global legislations, acquiring a permit to export e-waste in Australia is a difficult process. For instance, during 2009–2010, the Department of the Environment, Water, Heritage and Arts processed 14 permits to export hazardous wastes and 20 permits to import hazardous wastes. 16 of the permits were granted and four applications were refused as per their stringent rules (see “Relevant Websites section”). Currently, the export of e-waste to under developed countries is not a viable option (Figs. 13 and 14).

The trend of e-waste recycling is on the rise, yet still lagging behind with respect to Europe or USA. Around 40 collecting centres are working throughout the country (see “Relevant Websites section”). Sims metal management (SIMSMM) and Outotec are some firms which process e-waste for the recovery of metals. SIMSMM is the leading e-waste recycler that has facilities located in New South Wales, Victoria, Queensland and Western Australia. A robust recycling management system is required in Australia to deal with the large quantities of e-waste that will be generated as contemplated, in the future.

European Nations

Waste of electrical and electronic equipment, or EEE's such as computers, TV-sets, fridges and cell phones is one of the soaring waste streams in the countries under EU, with some 9 million tonnes generated in 200 (see “Relevant Websites section”), with an annual growth of 3%–5% per year which is estimated to reach the mark of 12 million tonnes by 2020 (see “Relevant Websites section”).

The European countries with the highest e-waste generation are Germany, the United Kingdom, France and Russia (Table 4). These countries are currently signatories of the Basel Convention and the export of e-waste is strictly curbed in these nations. The e-waste, generally was sent trans-boundaries finally landing in the developing countries of Africa such as Nigeria, Ghana, South

Africa etc., as a secondary export market. Being in the developing stage, they have under developed technological infrastructure for processing e-waste which severely affect the environment of the vicinity. These countries, after signing the Basel Convention, have strict import regulations, official banning these movements.

Uniform legislation regarding the collection and processing of e-waste has been restored efficiently in the EU by the directive 2012/19/EU of the European Parliament and of the council of 4th July 2012 on waste electrical and electronic equipment (WEEE) (see “Relevant Websites section”). The recast of the WEEE Directive (2012/19/EU), which ended into force on 13th August 2012, proposed an incremental increase in the collection of e-waste from 2016 till 2021. The projected annual collection target should be the relation between the collected amount and the average amount of EEE put on the market in the three preceding years.

In Germany, for instance, a mechanism known as “divided product responsibility” was instituted by the WEEE Directive for electrical and electronic waste disposal operations. This electronic waste disposal responsibility fell into the domains of public sector recycling companies and the EEE manufacturers. Public sector recycling companies were required to establish e-waste recycling centres and to accept such waste at these centres free of charge. This mechanism is currently carried out at around 1500 municipal recycling centres all over the country. Alternatively, manufacturers were free to provide their own recycling mechanisms, and retailers are also allowed to take back electrical and electronic waste. Consumers are subjected by law to take their discarded EEEs to such facilities. The current collection rate targets are set by the WEEE Directive which is currently set to 65%, for the year 2019 (see “Relevant Websites section”).

According to an Ökopol study that was commissioned by the German Environment Agency (Umweltbundesamt or UBA), in 2008 some 150,000 tons of electrical and electronic waste was exported from Germany to Nigeria, Ghana, India, South Africa and other countries. The new WEEE directive enforces the exporters to prove the functionality of devices declared as used prior to export, the purpose is to ensure only intact apparatuses are exported as their reuse shall save resources in the destination countries (see “Relevant Websites section”) (Table 5).

The Balkan region has often been the destination for e-waste disposal from the developed world. The practices of dealing with locally-generated e-waste were not environment friendly, which led to a loss of secondary resources and

Fig. 15 Distribution mapping of e-waste generation in European nations. Reproduced from Baldé, C.P., Wang, F., Kuehr, R., Huisman, J., 2015. *The Global E-Waste Monitor – 2014*. Bonn, Germany: United Nations University, IAS – SCYCLE.

damage of the environment. The National legislation on e-waste management has been put in force in five countries of this region: Montenegro, Macedonia, Serbia, and Bosnia and Herzegovina. There is no national legislation tackling e-waste in Kosovo, whereas the western Balkans region have not yet implemented an effective e-waste system like the other EU Member States. Further development in collection schemes and recycling infrastructure is of prime requirement in this region.

The situation in Belarus, Armenia, Kirgizstan and Russia is not quite clear. So far, they do not have any e-waste legislation or management system in place. Although, in 2014, Russia introduced EPR (extended product responsibility) as the stepping stone in e-waste management. Various inter-agency groups on regulations are currently active in making the implementation of such laws in the region (Figs. 15 and 16).

United States of America

The United States generated 11.7 million tons of e-waste, around 28% of the entire global production in the year 2014 (see “Relevant Websites section”). Among the world’s e-waste contributors, U.S. is the only country which has generated trash more than that of a few continents, such as South America, Africa Oceania etc. The country either disposes the wastes collected or exports them to the developing nations of Asia and Africa as well as Latin America. Currently, the latter trend is quite compelled by the entire world, as it is the only nation among developed world to sign, yet not ratify the Basel Convention, which restricts the trans-country movements of toxic wastes (see “Relevant Websites section”). The United States currently maintains a multilateral agreement with the members of the Organisation for Economic Co-operation and

Fig. 16 Distribution of e-waste generation per capita in North America. Reproduced from Baldé, C.P., Wang, F., Kuehr, R., Huisman, J., 2015. *The Global E-Waste Monitor – 2014*. Bonn, Germany: United Nations University, IAS – SCYCLE.

Development (OECD), governing transboundary movements of waste for recovery purposes. Moreover, it has established two bilateral agreements, with Canada and Mexico, for importing and exporting hazardous waste. In the end, Costa Rica, Malaysia and the Philippines have entered into separate understanding agreements with the United States, under which, United States may receive waste, but may not export e-waste to these countries respectively (Chapter-V, 2011).

Many states in the U.S. have begun efforts to collect for further processing from the residential and business sources. For instance, the State of California has passed a law in the year 2006, charging consumer fees, called Advanced Recycling Fees (ARFs), at the time of buying the products. The system covered monitors, TVs and laptops, and the ARF was between US\$ 6 and US\$ 10 (Gregory and Kirchain, 2007). Similar steps taken by different states have later helped in collecting e-wastes for recycling. Table 3 describes the data of the recycled e-waste among various states of the United States in the year of 2014 (Fig. 17).

After working systems, valuable components, and hazardous materials are removed from the e-waste, the materials recovery process begins. The primary goal of this process is to separate different types of materials that can be recovered and sold. Residential electronic waste collection programs in the U.S. show that the majority of the items collected consist of TVs, computers and monitors, and other appliances. The flow of materials after discarding the product for the market of USA can be understood from Fig. 18. The letters in the codes in italics in the figure refer to the state of the item, S, the activity, A, or the destination, D.

There are two domestic third party certification systems for e-waste recyclers in the country: R2 and E-Stewards. The electronics recycling industry is increasingly embracing these programs to improve their environmental performances and reduce human health impacts from improper recycling (Baldé et al., 2015).

Continuous and stable supply of materials is still the major challenge for e-waste recycling. Although, the development of cost effective technologies for recycling is of absolute necessity, existing methods have limited ability to handle complex products (Kang and Schoenung, 2005) (Fig. 19).

Whatever system is put in place, it also important that financial responsibility needed is ensured proper management. One issue is the management of the new financial flows. One option – in a strict interpretation of the idea of EPR – is to make manufacturers entirely responsible for collection and disposal. However, other participants in the chain of electronic products, such as consumers and government, should also take partial responsibility for e-waste management.

E-WASTE RECYCLED IN U.S (2014)

Introduction

Rubber plantation is first introduced in Malaysia even before the country achieved its independence. Rubber seedlings were brought into the country by the British, and were first planted at Kuala Kangsar, Perak. This area was chosen due to the condition of the terrain, which is suitable for rubber trees, and, within a few years, the cultivation of rubber had grown rapidly throughout the Malaysian peninsular.

Since independence in 1957, the Malaysian government has set up many agencies with an objective to modernize the agricultural industries including the rubber plantations. Federal Land Development Authority (FELDA) was given the task of initiating and managing rubber plantations to support the relocation of rural populations. In 1973, the government also established the Rubber Industry Smallholders Development Authority (RISDA). This agency was established with the aim of helping small rubber farmers to increase their income. Until 2010, RISDA brought together the rubber plantations owned by smallholders, and the records showed that the area planted with rubber trees reached up to 587,225 hectares. Moreover, FELDA has managed to open up new land for planting rubber trees, which reached an area of 65,932 hectares. However, several problems were faced by these agencies as well as by the rubber farmers themselves. According to the records, replanting the rubber trees took a long time, and the rubber farmers had to wait for months before they could tap the trees. Furthermore, the farmers were also affected due to the volatile price of rubber in the market. In 2011, Malaysia produced approximately 9% of the total amount of rubber materials produced worldwide which was equivalent to 996,000 metric tonnes of rubber. This number indicated that Malaysia was the third-largest country in the world for rubber production.

Recently, the price of natural rubber (NR) has fallen drastically because of advancements in synthetic rubber. As a result, the rubber farmers must bear huge losses and this situation affects their monthly income. The authorities are demanded to take appropriate action to help the farmers who facing these economic difficulties. Research institutions and universities are also required to participate actively in finding solutions to increase the value and usage of NR. It is also essentially important for more extensive research in finding the use of NR in more appropriate products. This will consequently result in an increase in the price of NR, in line with the main objective, that is to improve the farmers' income. Conservative study needs to be revolutionized with innovative research while maintaining the key characteristics of the NR itself.

Currently, there are over 3500 articles discussing the use of NR as vibration isolators in dissipating energy, by considering various combinations of restoring and damping forces applied on the system. Many researchers are developed an exact solution for vibratory response called symmetric system, which consist of coulomb and viscous damping (Bhuiyan *et al.*, 2010; Carrella, 2011; Burdzik, 2014). Both damping was subjected to a harmonic motion. Based on these two studies, the magnitude of stiffness required in designing the new vibration isolators is found and transmissibility force could be predicted by referring to the resonant amplitudes.

The development of passive mechanical vibration isolator consisting of discrete mass, stiffness, and damping elements have initiated approximately 30 years ago. This system is similar to the lumped parameter system. It was discovered that the effectiveness of the vibration isolators was when the system was subjected to a harmonic excitation in certain frequency ranges. The resonances of the isolator are similar compared to previous researches and the level of transmitted force was further reduced (Chang, 2002; Mitra *et al.*, 2010; Du *et al.*, 2011; Karabork, 2011; Kobayashi *et al.*, 2012).

Vibration isolators have been widely to suppress the level of vibration, especially in building structures for earthquake protection. It is made from layers of rubber with thin steel plates between them, and a thick plate located at the top and bottom of the rubber materials. These vibration isolators are located between the bottom of a building and its foundation. By embedding the metal plates, the combination provides better performance in terms of stress and strain level when a heavy load is applied and prevents a bulging effect in the horizontal direction. It is also designed to be very stiff and strong for vertical load; therefore, it can carry the heavy weight of the building. In addition, this study also investigates the effect of the shape factor on the stress distributions and stress concentration of the NR elastomer subjected to longitudinal load. The finite element analysis (FEA) approach was used to produce an approximated solution. The results obtained from numerical modeling is then compared and validated with an analytical approximated solution (Kobayashi *et al.*, 2012). Based on this correlation study, it was found that a beneficial effect of the shape factor was higher stress distribution and stress concentration parallel with the reduction of edge effects (Kobayashi *et al.*, 2012). This study is in good agreement with past research in the use of rubber bearings to support bridges being built as part of new highway construction in Greece (Ibrahim, 2008). Two samples of

rubber bearings were located at the bridge columns. The test results revealed that the stiffness and damping ratio show a good relationship with longitudinal load as well as the frequency of the horizontal displacement. It was found that by employing the isolation strategy, the superstructure motion was decoupled from the pier's motion during an earthquake. The inertia forces could be reduced and at the same time, energy was dissipated by the vibration isolators, which, finally, reduced the acceleration transmitted into the superstructure.

In addition, in 2007, the model of the hysteretic behaviour of rubber bearings under unidirectional horizontal displacement and constant horizontal compressive load was proposed. Three types of bearing were used in these studies, namely NR bearing, lead rubber bearing and high-damping rubber bearing. Several experiments were conducted to analyse the performance of the bearings, such as basic test, multi-step relaxation, cyclic test and simple relaxation. It was found that the NR bearings gave the best result in terms of the rate-dependent rheology. This represents the typical shear stress-strain responses of high-damping rubber bearings where the strain rate dependency of hysteresis occurs (Bhuiyan *et al.*, 2010).

The new design of vibration isolators is needed to increase the performance of the isolator by shifting the resonance frequency, thus increasing the effectiveness of the isolator. Based on the previous study, the mathematical modeling of the vibration isolator could be derived by using wave propagation approach (Yin *et al.*, 2010; Mishra and Igarashi, 2013; Lee *et al.*, 2014; Salim *et al.*, 2014). The non-dispersive finite rod was chosen as a vibration isolator model, and it was represented as rubber material isolator. Impedance matrix was developed to evaluate and investigate the internal resonance behaviour of the isolator. The waves were propagated from the initial boundary of non-dispersive finite rod, and bounced back to the initial location. It happened due to the natural behaviour of waves. It could not pass the end of the boundary which was fixed.

This phenomenon has also been discussed previously. Researchers agreed that the natural behaviour of the waves could not pass the fixed boundary, and not affecting the vibration isolator performance (Yan *et al.*, 2007; Peng *et al.*, 2010; Sun and Zhang, 2013; Spizzuoco *et al.*, 2014; Sun *et al.*, 2014).

This article focuses on the performance and characteristics of vibration isolator based on the discrete lumped parameter model. This model is adopted from conventional lumped parameter model with some modification. Reynolds and Falkenberg (1984) applied the lump parameter model to evaluate the vibration response characteristics on human hand while operating chipping and grinding process. By using the discrete lumped parameter model in vibration isolator application, it is expected to contribute in characterizing the vibration isolators' performance and transmissibility behaviour subjected to the longitudinal vibration.

Modeling and Prediction Estimation of Discrete Lumped Parameter Model

This section focuses on the development of the discrete lumped parameter model which is adopted from the conventional lumped parameter model. The intention is to model the isolator into discrete springs and masses to take into account the effect of inertial mass. The distributed mass is assumed to have total mass equivalent to the mass of the isolator, and the stiffness value was according to the height of the isolator which was based on the value of the overall stiffness. The excitation force F_e , transmitted force F_t and, finally, displacement u were used in this system.

Distributed parameter model is used as a benchmark to develop the discrete lumped parameter system. Fig. 1 shows the modified distributed parameter isolator compared to the discrete lumped parameter models.

The equation of motion for the discrete lumped parameter system can be given as

$$F_e = M\ddot{u}_1 + ku_1 \quad (1)$$

and

$$F_t = ku_1 \quad (2)$$

In harmonic motion, both equations of motion in Eqs. (1) and (2) become

$$F_e = -\omega^2 MU_1 + kU_1 \quad (3)$$

and

$$F_t = kU_1 \quad (4)$$

where, U is the complex amplitude, ω is the frequency, F_e is excitation force and F_t is transmitted force.

The general transmissibility equation is

$$T_r = \left| \frac{F_t}{F_e} \right| \quad (5)$$

By inserting Eqs. (3) and (4) into (5), the transmissibility equation for the single-degree-of-freedom for the discrete lumped parameter system can be given as

$$T_r = \left| \frac{kU_1}{-\omega^2 MU_1 + kU_1} \right| \quad (6)$$

Fig. 1 Discrete lumped parameter models (a) Distributed parameter isolator and (b) Discrete lumped parameter models.

Therefore, the steps from Eqs. (1)–(6) can be used in developing the higher-degree-of-freedom of the system.

Multi-Degree-of-Freedom

In this section, the multi-degree-of-freedom of the discrete lumped parameter model is discussed, and the aim is to develop the internal resonance behaviour. For the two-degree-of-freedom discrete lumped parameter system, the rubber (see Fig. 1(b)) was divided into two spring elements. However, the total value of stiffness and mass remained the same as in the single-degree-of-freedom system. Fig. 2 illustrates the schematic diagram for the two-degree-of-freedom discrete lumped parameter model. The equations of motion for the systems can be derived as

$$F_e = M\ddot{u}_1 + \frac{k}{2}u_1 - \frac{k}{2}u_2 \quad (7)$$

$$0 = m\ddot{u}_2 + \frac{k}{2}u_2 - \frac{k}{2}u_1 \quad (8)$$

and

$$F_t = \frac{k}{2}u_2 \quad (9)$$

In harmonic motion, Eqs. (7)–(9) become

$$F_e = -\omega^2 MU_1 + \frac{k}{2}U_1 - \frac{k}{2}U_2 \quad (10)$$

$$0 = -\omega^2 mU_2 + \frac{k}{2}U_2 - \frac{k}{2}U_1 \quad (11)$$

and

$$F_t = \frac{k}{2}U_2 \quad (12)$$

Fig. 2 Two-degrees-of-freedom discrete lumped parameter model.

By simplifying Eqs. (10) and (11), the new equations are given by

$$F_e = \left(\frac{k}{2} - \omega^2 M \right) U_1 - \frac{k}{2} U_2 \quad (13)$$

and

$$0 = \left(\frac{2k}{2} - \omega^2 m \right) U_2 - \frac{k}{2} U_1 \quad (14)$$

By taking U_2 as a reference for U_1 , therefore Eq. (14) can be written and then simplified as

$$U_1 = \left(2 - \frac{2}{k} \omega^2 m \right) U_2 \quad (15)$$

Then, to solve Eq. (13), Eq. (15) is used, and, finally, the new equation becomes

$$F_e = \left(\frac{k}{2} - \omega^2 M \right) \left(2 - \frac{2}{k} \omega^2 m \right) U_2 - \frac{k}{2} U_2 \quad (16)$$

Again, by taking Eq. (5) as a reference, the transmissibility equation for the two-degree-of-freedom discrete lumped parameter of the isolator, is given by

$$T_r = \left| \frac{F_t}{F_e} \right| = \left| \frac{\frac{k}{2} U_2}{\left(\frac{k}{2} - \omega^2 M \right) \left(2 - \frac{2}{k} \omega^2 m \right) U_2 - \frac{k}{2} U_2} \right| \quad (17)$$

For the three-degree-of-freedom discrete lumped parameter system, the stiffness value was divided into three parts of spring element and the mass of the rubber is divided into two. However, the total mass is equivalent to the total mass of the two-degree-of-freedom discrete lumped parameter system. Fig. 3 shows the schematic diagram of the system.

Then, the equation of motion of this system can be given as

$$F_e = M \ddot{u}_1 + \frac{k}{3} u_1 - \frac{k}{3} u_2 \quad (18)$$

$$0 = \frac{m}{2} \ddot{u}_2 + \frac{2k}{3} u_2 - \frac{k}{3} u_1 - \frac{k}{3} u_3 \quad (19)$$

$$0 = \frac{m}{2} \ddot{u}_3 + \frac{2k}{3} u_3 - \frac{k}{3} u_2 \quad (20)$$

and

$$F_t = \frac{k}{3} u_3 \quad (21)$$

For harmonic motion, Eqs. (18)–(21) become

$$F_e = -\omega^2 M U_1 + \frac{k}{3} U_1 - \frac{k}{3} U_2 \quad (22)$$

Fig. 3 Three-degree-of-freedom discrete lumped parameter model.

$$0 = -\omega^2 \frac{m}{2} U_2 + \frac{2k}{3} U_2 - \frac{k}{3} U_1 - \frac{k}{3} U_3 \quad (23)$$

$$0 = -\omega^2 \frac{m}{2} U_3 + \frac{2k}{3} U_3 - \frac{k}{3} U_2 \quad (24)$$

and

$$F_t = \frac{k}{3} U_3 \quad (25)$$

By simplifying Eqs. (22)–(24), the equations can be written as

$$F_e = \left(\frac{k}{3} - \omega^2 M \right) U_1 - \frac{k}{3} U_2 \quad (26)$$

$$0 = \left(\frac{2k}{3} - \omega^2 \frac{m}{2} \right) U_2 - \frac{k}{3} U_1 - \frac{k}{3} U_3 \quad (27)$$

and

$$0 = \left(\frac{2k}{3} - \omega^2 \frac{m}{2} \right) U_3 - \frac{k}{3} U_2 \quad (28)$$

By taking U_3 as a reference of U_2 , therefore, the new equation can be derived as

$$U_2 = \left(2 - 3\omega^2 \frac{m}{k} \right) U_3 \quad (29)$$

On the other hand, from Eq. (27), U_2 and U_1 can be written as a reference for U_3 . After rearranging the equation, finally, it can be given as

$$U_3 = \left(2k^2 - \frac{3}{2}\omega^2 mk \right) U_2 - k^2 U_1 \quad (30)$$

By substituting Eq. (30) into Eq. (29), the equation can be written as

$$U_2 = \frac{-k^2}{1 - \left(2 - 3\omega^2 \frac{m}{k} \right) \left(2k^2 - \frac{3}{2}\omega^2 mk \right)} U_1 \quad (31)$$

Then, by inserting Eq. (29) into Eq. (31), the equation becomes

$$\left(2 - 3\omega^2 \frac{m}{k} \right) U_3 = 2 = \frac{-k^2}{1 - \left(2 - 3\omega^2 \frac{m}{k} \right) \left(2k^2 - \frac{3}{2}\omega^2 mk \right)} U_1 \quad (32)$$

By simplifying Eq. (32), it can be written as

$$U_1 = \frac{\left(2 - 3\omega^2 \frac{m}{k} \right) U_3 \times \left[1 - \left(2 - 3\omega^2 \frac{m}{k} \right) \left(2k^2 - \frac{3}{2}\omega^2 mk \right) \right]}{-k^2} \quad (33)$$

By substituting Eqs. (29) and (33) into Eq. (26), it becomes

$$F_e = \left(\frac{k}{3} - \omega^2 M \right) \times \frac{(2 - 3\omega^2 \frac{m}{k}) U_3 \times [1 - (2 - 3\omega^2 \frac{m}{k})(2k^2 - \frac{3}{2}\omega^2 mk)]}{-k^2} - \frac{k}{3} \left(2 - 3\omega^2 \frac{m}{k} \right) U_3 \quad (34)$$

By simplifying Eq. (34), the equation of excitation force becomes

$$F_e = \left(\frac{k}{3} - \omega^2 M \right) \left(2 - \frac{3}{k} \omega^2 m \right) U_3 - \frac{k}{3} U_3 \quad (35)$$

Therefore, the transmissibility equation of the three-degree-of-freedom discrete lumped parameter model can be written as

$$T_r = \left| \frac{F_t}{F_e} \right| = \left| \frac{\frac{k}{3} U_3}{\left(\frac{k}{3} - \omega^2 M \right) \left(2 - \frac{3}{k} \omega^2 m \right) U_3 - \frac{k}{3} U_3} \right| \quad (36)$$

Consequently, by dividing into three parts of the rubber mass, and dividing the stiffness into four parts of spring elements, the system is represented as four-degree-of-freedom discrete lumped parameter system. However, the total value for stiffness and mass remained the same as previous system. Fig. 4 shows the schematic diagram of the system. The equations of motion for the system are as expressed in Eqs. (37)–(41).

$$F_e = M\ddot{u}_1 + \frac{k}{4}u_1 - \frac{k}{4}u_2 \quad (37)$$

$$0 = \frac{m}{3}\ddot{u}_2 + \frac{2k}{4}u_2 - \frac{k}{4}u_1 - \frac{k}{4}u_3 \quad (38)$$

$$0 = \frac{m}{3}\ddot{u}_3 + \frac{2k}{4}u_3 - \frac{k}{4}u_2 - \frac{k}{4}u_4 \quad (39)$$

$$0 = \frac{m}{3}\ddot{u}_4 + \frac{2k}{4}u_4 - \frac{k}{4}u_3 \quad (40)$$

and

$$F_t = \frac{k}{4}u_4 \quad (41)$$

Following this, in harmonic motion, the equations of motion become

$$F_e = -\omega^2 M U_1 + \frac{k}{4}U_1 - \frac{k}{4}U_2 \quad (42)$$

$$0 = -\omega^2 \frac{m}{3} U_2 + \frac{2k}{4}U_2 - \frac{k}{4}U_1 - \frac{k}{4}U_3 \quad (43)$$

$$0 = -\omega^2 \frac{m}{3} U_3 + \frac{2k}{4}U_3 - \frac{k}{4}U_2 - \frac{k}{4}U_4 \quad (44)$$

Fig. 4 Four-degree-of-freedom discrete lumped parameter model.

$$0 = -\omega^2 \frac{m}{3} U_4 + \frac{2k}{4} U_4 - \frac{k}{4} U_3 \quad (45)$$

and

$$F_t = \frac{k}{4} U_4 \quad (46)$$

By simplifying Eqs. (42)–(45), the equations are given by

$$F_e = \left(\frac{k}{4} - \omega^2 M \right) U_1 - \frac{k}{4} U_2 \quad (47)$$

$$0 = \left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) U_2 - \frac{k}{4} U_1 - \frac{k}{4} U_3 \quad (48)$$

$$0 = \left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) U_3 - \frac{k}{4} U_2 - \frac{k}{4} U_4 \quad (49)$$

and

$$0 = \left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) U_4 - \frac{k}{4} U_3 \quad (50)$$

From Eq. (49), U_3 and U_4 can be written as a reference for U_2 . Therefore, by rearranging the equation, it then becomes

$$U_2 = \left(2k^2 - 4\omega^2 \frac{m}{3} k \right) U_3 - k^2 U_4 \quad (51)$$

By rearranging Eq. (50), and letting U_3 be a reference value of U_4 , finally, the equation can be expressed as

$$U_4 = \frac{k}{4} \left(\frac{1}{\frac{2k}{4} - \omega^2 \frac{m}{3}} \right) U_3 \quad (52)$$

By substituting Eq. (52) into Eq. (51), it gives

$$U_2 = \left(2k^2 - 4\omega^2 \frac{m}{3} k \right) U_3 - k_2 \left[\frac{k}{4} \left(\frac{1}{\frac{2k}{4} - \omega^2 \frac{m}{3}} \right) \right] U_3 \quad (53)$$

By inserting Eq. (53) into Eq. (49), then the equation becomes

$$0 = \left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) U_3 - \frac{k}{4} \left(2k^2 - 4\omega^2 \frac{m}{3} k \right) U_3 - k_2 \left[\frac{k}{4} \left(\frac{1}{\frac{2k}{4} - \omega^2 \frac{m}{3}} \right) \right] U_3 - \frac{k}{4} U_4 \quad (54)$$

By rearranging Eq. (54), the equation becomes

$$U_3 = \frac{U_2 + k^2 U_4}{2k^2 - 4\omega^2 \frac{m}{3} k} \quad (55)$$

By inserting Eq. (55) into Eq. (54), the equation can be written as

$$\begin{aligned} 0 = & \left[\left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) \times \left(\frac{U_2 + k^2 U_4}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \right] - \left[\frac{k}{4} \left(2k^2 - 4\omega^2 \frac{m}{3} k \right) \times \left(\frac{U_2 + k^2 U_4}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \right] \dots \\ & \dots - k_2 \left[\frac{k}{4} \left(\frac{1}{\frac{2k}{4} - \omega^2 \frac{m}{3}} \right) \times \left(\frac{U_2 + k^2 U_4}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \right] - \frac{k}{4} U_4 \end{aligned} \quad (56)$$

By dividing Eq. (56) into small groups, they become

$$G1 = \left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) \times \left(\frac{U_2 + k^2 U_4}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \quad (57)$$

$$G2 = \frac{k}{4} \left(2k^2 - 4\omega^2 \frac{m}{3} k \right) \times \left(\frac{U_2 + k^2 U_4}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \quad (58)$$

$$G3 = k_2 \left[\frac{k}{4} \left(\frac{1}{\frac{2k}{4} - \omega^2 \frac{m}{3}} \right) \times \left(\frac{U_2 + k^2 U_4}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \right] \quad (59)$$

and

$$G4 = \frac{k}{4} U_4 \quad (60)$$

By substituting Eq. (55) into Eq. (48), the equation can be expressed as

$$0 = \left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) U_2 - \frac{k}{4} U_1 - \frac{k}{4} \left(\frac{U_2 + k^2 U_4}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \quad (61)$$

By simplifying Eq. (61), the equation becomes

$$U_2 = \frac{\left(\frac{k^3 U_4}{8k^2 - 16\omega^2 \frac{m}{3} k} \right) - \frac{k}{4} U_1}{\left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) - \left(\frac{1}{8k^2 - 16\omega^2 \frac{m}{3} k} \right)} \quad (62)$$

By inserting Eq. (62) into Eqs. (57)–(59), the equations become

$$G1 = \left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) \times \frac{\left(\frac{k^3 U_4}{8k^2 - 16\omega^2 \frac{m}{3} k} \right) - \frac{k}{4} U_1}{\left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) - \left(\frac{1}{8k^2 - 16\omega^2 \frac{m}{3} k} \right)} + k^2 U_4 \times \left(\frac{1}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \quad (63)$$

$$G2 = \frac{k}{4} \left(2k^2 - 4\omega^2 \frac{m}{3} k \right) \times \frac{\left(\frac{k^3 U_4}{8k^2 - 16\omega^2 \frac{m}{3} k} \right) - \frac{k}{4} U_1}{\left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) - \left(\frac{1}{8k^2 - 16\omega^2 \frac{m}{3} k} \right)} + k^2 U_4 \times \left(\frac{1}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \quad (64)$$

and

$$G3 = k_2 [A \times B + C] \quad (65)$$

where

$$A = \frac{k}{4} \left(\frac{1}{\frac{2k}{4} - \omega^2 \frac{m}{3}} \right) \quad (66)$$

$$B = \frac{\left(\frac{k^3 U_4}{8k^2 - 16\omega^2 \frac{m}{3} k} \right) - \frac{k}{4} U_1}{\left(\frac{2k}{4} - \omega^2 \frac{m}{3} \right) - \left(\frac{1}{8k^2 - 16\omega^2 \frac{m}{3} k} \right)} \quad (67)$$

and

$$C = k^2 U_4 \times \left(\frac{1}{2k^2 - 4\omega^2 \frac{m}{3} k} \right) \quad (68)$$

By simplifying Eqs. (63)–(65), and inserting the simplified group into Eq. (56), and finally transferring the equation into Eq. (45), the excitation force equation becomes

$$F_e = \left(\frac{k}{4} - \omega^2 M \right) \left(2 - \frac{4}{k} \omega^2 m \right) U_4 - \frac{k}{4} U_4 \quad (69)$$

Finally, the transmissibility equation for four-degree-of-freedom discrete lumped parameter system can be written as follow

$$T_r = \left| \frac{F_t}{F_e} \right| = \left| \frac{\frac{k}{4} U_4}{\left(\frac{k}{4} - \omega^2 M \right) \left(2 - \frac{4}{k} \omega^2 m \right) U_4 - \frac{k}{4} U_4} \right| \quad (70)$$

By observing Eqs. (6), (17), (36) and (70), there is a relationship regarding the pattern of the transmissibility equation for two-degree-of-freedom discrete lumped parameter model and onwards. However, it is very hard to derive the discrete lumped parameter model by dividing the mass of rubber at higher number. The general equation of discrete lumped parameter model for higher-degree-of-freedom can be represented as given in Eq. (71).

$$T_r = \left| \frac{F_t}{F_e} \right| = \left| \frac{\frac{k}{N} U_N}{\left(\frac{k}{N} - \omega^2 M \right) \left(2 - \frac{N}{k} \omega^2 m \right) U_N - \frac{k}{N} U_N} \right| \quad (71)$$

where N is a number of degree-of-freedom of discrete lumped parameter system.

Additionally, the stiffness value for the discrete lumped parameter model is obtained from the stiffness value of the non-dispersive finite rod.

Performance Evaluation

This section presents the baseline results and higher order results for discrete lumped parameter models.

Baseline Models

Fig. 5 shows the result for single-degree-of-freedom discrete lumped parameter model. The natural frequency located at 10 Hz, and the graph went below 10^0 . The roll-off rate for the model was recorded at 20 dB per decade, and it was similar to the roll-off rate that was captured in the conventional lumped parameter system Eqs. (11)–(13). Meanwhile, Fig. 6 shows the results for two-degree-of-freedom discrete lumped parameter model. The first natural frequency remained at 10 Hz. The second natural frequency

Fig. 5 Transmissibility of one-degree-of-freedom for discrete lumped parameter model.

Fig. 6 Transmissibility of two-degree-of-freedom for discrete lumped parameter model.

located approximately at 120 Hz. Figs. 7 and 8 shows the results for three- and four-degree-of-freedom discrete lumped parameter models. The first natural frequency for both models remained at 10 Hz. However, three-degree-of-freedom model showed the second and third natural frequencies at 110 Hz and 125 Hz, respectively. In four-degree-of-freedom model, the second, third and fourth natural frequencies were located at 110 Hz, 120 Hz and 135 Hz. The roll-off rate for both models were same as conventional lumped parameter models Eqs. (11)–(13).

By using this pattern, it is believed that by increasing the number of metal plates embedded in discrete lumped parameter model, the second natural frequency onwards and the internal resonance of the system can be evaluated in higher-degree-of-freedom models.

Fig. 7 Transmissibility of three-degree-of-freedom for discrete lumped parameter model.

Fig. 8 Transmissibility of four-degree-of-freedom for discrete lumped parameter model.

Higher-Degrees-of-Freedom

The numerical software was used to derive the excitation force of the discrete lumped parameter model when dividing original rubber mass at higher order. Fig. 9 shows the results when dividing the mass of rubber into eight parts. The natural frequency for each graph remained at 10 Hz, and then the graphs went below 10^0 . However, at 900 Hz, the transmissibility increased and was close to unity, where the peaks were obtained at 1380 Hz, and, finally, it refrained below 10^{-2} . Additionally, this only occurred at high frequencies. The roll-off rate was recorded at 20 dB per decade, and it was similar to the roll-off rate that was captured in the conventional lumped

Fig. 9 Result for dividing rubber mass into 8 parts.

Fig. 10 Result for dividing rubber mass into 12 parts.

parameter system Eqs. (11)–(13). Furthermore, in this model, the second natural frequency can also be recognized as a first peak of the internal resonance, and it will be used as an indicator to investigate the vibration performance in the future.

By dividing the rubber mass of the model into 12 parts, the first and second natural frequencies were positioned at 80 Hz and 6000 Hz, respectively. The internal resonance peaks of the model appeared in high frequency range. Then, rubber mass of the model was also divided into 16 parts, and the fourth natural frequency was located approximately at 10,500 Hz. Next, the rubber mass of the model was divided into more parts which were 20, 32 and 41, and the internal resonance peaks were observed. Therefore, this internal resonance can be used to evaluate and investigate the performance and the characteristics of the discrete lumped parameter models in future. All of the results are shown in Figs. 10–14, respectively.

Fig. 11 Result for dividing rubber mass into 16 parts.

Fig. 12 Result for dividing rubber mass into 20 parts.

Fig. 13 Result for dividing rubber mass into 32 parts.

Fig. 14 Result for dividing rubber mass into 41 parts.

Conclusion

In this study, it proves that Natural Rubber (NR) can be used as vibration isolator and the characteristics of specific parameters can be determined. The vibration isolator modeling estimation and performances have been investigated by using discrete lumped parameter model. By dividing the higher number of mass inside the model, the internal resonance behaviour can be evaluated. This behaviour is very critical in determining the overall performance and characteristics of vibration isolator. However, it only appears at high frequency range which is around 400 Hz. There are some assumptions that have been made such as the total mass

of the model is equivalent with the mass of the vibration isolator. The stiffness amount is assumed according to the height of the vibration isolator, and based on the overall stiffness of the isolator. All of these assumptions are very important in order to model the discrete lumped parameter and finally in evaluating the transmissibility results.

Modeling of Information System for Air Waste Management

Dalibor Petković, University of Niš, Pedagogical Faculty in Vranje, Partizanska, Vranje, Serbia

© 2020 Elsevier Inc. All rights reserved.

Introduction

The increasing trend in the consumption of various materials has also led to a huge increase in the air waste and the consequent environmental pollutions in particular greenhouse gas emissions. These have made air waste management a significant environmental issue for governments and policy-makers. To address these challenges, developed countries have implemented sustainable material management strategies which have been comprehensively reviewed herein. However, there is need to integrate the strategies in one information system for easy application.

An integrated system for waste reduction, collection, composting, recycling, and disposal is required to tackle the growing challenge of air waste management. Integrated air waste management involves many executive, operational and managerial decisions such as the siting of waste processing and disposal units, selection of waste-treatment technologies and allocation of waste flow to processing facilities and landfills.

Waste management process could be very complex task because of many different suppliers and collectors. Suppliers could be industrial buildings which produce large masses of air waste and collectors should reduce the air wasted. There is need to make optimal route for the most efficient transport of the waste to the collectors. In other word there is need to find the most efficient way to detect and decrease the air wasted. The main problem is suppliers motivation for such a process since they require simple and understandable process for the air waste management. It is suitable to model an software which will make more motivation for suppliers and collectors to make stronger and more uniform connections. The software could determine the optimal routes and treatments for the waste based on locations of suppliers. In this article object orientated approach is used for the software modeling (Lethbridge and Laganier, 2005; Jacobson, 1993).

Object-orientated modeling strategy is an attempt to encapsulate data and process into thing called objects. The data in the objects could be created, deleted or used only by some encapsulated processes or methods. Unified modeling language (UML) is a standard tool for object orientated modeling which could help to developers and engineers to make detailed specification and documentation of any system.

UML (Rumbaugh *et al.*, 2004) is a graphical language which is effective for visualization, specification, construction and documentation of a system's artifact which is software intensive. UML has standard practices for writing a blueprint of system. By using UML one can cover various conceptual things such as functionality by use cases and business processes.

Modeling and analyzing of various activities in any system by UML can help to visualize, specify, constructs and document the system artifact effectively which is helpful for better understanding of the problem and for various stakeholders of the application of the air waste management.

Literature Overview of Air Waste Management

Factors influencing the diurnal atmospheric concentrations and soil-air exchange of polybrominated diphenyl ethers (PBDEs) were investigated at an e-waste recycling site in China during winter and summer (Wang *et al.*, 2017). In study (Giovannis, 2015) was examined the relationship between recycling rate of solid waste and air pollution using data from a waste municipality survey in the state of Massachusetts during the period 2009–2012. The effect of low excess air and high adiabatic combustion temperatures on CO and NO_x formation was investigated on a commercially operated energy-from-waste plant (Strobel *et al.*, 2017). With optimal combination of low O₂ levels and stable combustion control, uncontrolled NO_x levels could be lowered to 100–150 mg/Nm³ (dry, at 11% O₂) while keeping CO emissions at low levels (Strobel *et al.*, 2017). Three pilot-scale lysimeters were operated for 4.5 years to quantify the change in the carbon and nitrogen pool in an old landfill under various air injection conditions and the results indicated that air injection at the bottom layer facilitated homogeneous distribution of oxygen in the waste matrix (Wu *et al.*, 2016). An experiment for five stages of a biofilter-run was performed to investigate the effect of hydrophilic ethanol and hydrophobic toluene on the biodegradation of hydrophobic toluene and hydrophilic ethanol, respectively, when waste-air containing toluene and ethanol was treated by a biofilter (Lim, 2005). In paper (Lin *et al.*, 1994), the feasibility of application of a solid-absorption system using ammonia and chlorides as working pair to automobile air-conditioning system was investigated. This system has the advantages of minimum environmental problem and utilizing waste heat from the automobile engine as thermal energy input (Lin *et al.*, 1994). Hydrogen sulphide, ammonia, nitrogen dioxide, mercaptans and sulphur dioxide (H₂S, NH₃, NO₂, R-SH, SO₂) concentrations were measured at the location in the vicinity of the waste dump to determine the air pollution level of these pollutants prior to the operation of the Mobile Thermal Treatment Plant (Vadić *et al.*, 2000). The accumulation capacity for hydrophobic compounds of absorption agents employed in biological waste air purification was substantially affected by the varnish particles contained in the scrubbing liquid (Feige *et al.*, 1991).

Materials and Methods

Air Waste Management

According to the European Union standardization there are six procedures in the air waste treatment process:

1. Eco-design,
2. Air waste decreasing,
3. Air waste reusing,
4. Recycling and making compost,
5. Energy from air waste,
6. Air waste disposing.

The main activity of the investigation is to develop two separate softwares in order to make sustainable air waste management. In order to optimize the system for air waste management based on decreasing of pollution of life environment and for the cheapest solution there is goal to develop and model the software for the air waste management process. This innovative solution could lead to revolution in the air waste issue. By entering of the main data for air waste, quantity and composition for the some region, the client could know which is the best solution for the air waste treatment and transport for the region. Several air waste treatments are included in the software:

- Recycling,
- Combusting,
- Making compost,
- Performing anaerobic digestion and
- Disposing of air waste.

There are several indicators which are calculated in the software according the input data. These indicators are:

- Global warming,
- Heavy metals emission,
- Nitrogen oxide emission,
- Smog formation,
- Water pollution.

Therefore these software has seven modules. These modules:

- Calculation of emissions from collection and transport of air waste,
- Calculation of emissions from anaerobic digestion,
- Calculation of emissions from combustion,
- Calculation of emissions from recycled waste,
- Calculation of emissions from disposal,
- Calculation of emissions from compost,
- Calculation of cost benefit.

There is also plan to integrate the module for determination of the optimal route of the air waste transport. The optimization of the route is very important since there is constantly changing of the urban parameters: number of residents, waste quantity, type of transport vehicle, transport conditions. Clark and Wright savings algorithm could be applied for the route optimization for the air waste.

This software approach for the air waste management could be very helpful for managers who control waste, companies which produce and transport the waste and for decision makers to select the optimal scenery for the waste treatment and transport for each region. The main goals of the investigation are:

- Removing of the barriers for the decreasing of pollution of life environment by unsuitable treatment of the air waste.
- Increasing of ecological awareness for the importance of regular treatment of waste.
- Solving of problem of air waste collection and transport.

Specific goal of the investigation is:

- Modeling of innovative software as a tool for determination of a right strategy for air waste management.

Software Development for Air Waste Management

Generally, the software development methodology is consisted of procedures, technics, tools and documentation which helps in the software development process. Software development methodology describes all steps and phases of the software development. The methodology suggest tools and technics which should use in the particular step of the software development. Also the methodology could suggest how to plan and track process of the software development and testing as well.

Many companies use the methodologies for software development in order to ensure the consistency of the problem solution, to decrease the possible errors, to acquire the full documentation for current and future projects and to get good final product which could be changeable and adaptable easily since the all steps and phases would be documented in detail and any new changes in the software models could be achieved before software coding.

Models could be describes as simplified presentation of reality. The models could be presented with some standard modeling language. The model presentation could be textual or graphical by diagrams. Each software could be described based on different aspects by structural models in order to show software structure with the main parts and their interconnections and relationships. Also there is behaviour models where one can track the software dynamics.

RUP methodology

Rational Unified Process (RUP) is an iterative methdology for the software development based on architcture and use cases. RUP methdology is based on Unified Modeling Language (UML). UML is used for specification, visualization, construction and documentation of the software development.

RUP methodology has control, key or critical points throught the development. In the other words each phase of the RUP methdology should end by some control, key or critical points where achieved results are summed and future directions are planned based on the results. RUP methodology has artefacts (documents), models i model elements. Project requests are noted in the documents. Models are used to simplify the software architecture without unnecessary details. Model elements could help to visualize, construct and document the main structure and software behaviour.

RUP methodology has four main phases. The first phase is initial phase or idea inception where one needs to understand what should to do and software vision and requirements are identified. This phase includes the identification of key software actors (users) and use cases. Also there is need to identify software domain. Use case defines one sequence of an action which software performs that yields to an observable results. In the other hands one use cass presents result of an action by actor (Fig. 1). Use case presents the main part of some complete software operation from beginning until to the end. It is used to capture the intended behaviour of the system in development. By use cases models desired behaviour of the system could be specified but it is not strictly this desired behaviour to be carried out or implemented in the final product. Use cases models can be developed for whole system or for the part of system. Each part of system or subsystem can be developed by use cases models until the part produces some tangible amount of work and results. System complexity indicates the number of use cases. In the initial stage of system development main use cases are developed and additional use cases can be added or included when there is need for them.

The second phase is project elaboration where one needs to understand how to build the software and basic software architcture is showed in the phase. The third phase presents software construction where software testing is considered. The fourth phase presents software transition where software validation is performed.

RUP models describes software in modeling. RUP models could be business models which describes business processess and business environment, use case models which describes what software doing and software environment, projecting models which describes use cases realization as code abstraction and implementation models which presents collection of components and subsystems.

Software development process could has different problems which needs to be identifies and solved before coding and testing. In order to solve problems there is need to find the problem causes. To remove the problem causes it is suitable to use best practices. For example in order to remove the confusion in communication between team members it is suitable to use standard language UML for the software visualization, specification and documentation. There are different types of UML diagrams which can be used in the software development process. There are two main classes of the ULM diagrams. These are structural and behavioral diagrams. Structural diagram presents structure of the system in passive state and behavioral diagram present the active behaviour of the objects in a system or dynamical state.

Object-orientated modeling of business process

UML is used for object-orientated modeling of business process. As already mentioned there are different UML diagrams for describing of software architecture and software behaviour. UML as standard language is used for modeling, for analyzing, for projecting and for implementation of the software system. Based on the object-orientated modeling all process could be presented by use cases models as rough specification and by structural diagrams and behavioral diagrams as detail specification.

During modeling of the business process it is not recommended to use natural language because of its ambiguity. Also formal programming languages is not understandable for many people in the project team. Therefore it is suitable to organize the natural language to avoid ambiguity. Modeling process is one of the solution for understanding and clear communication between project team members.

Fig. 1 Use case model.

Modeling of the Air Waste Management

Problem Description

The problem is intended for solving of treatment and transport of air waste. The main objects of the model are clients, administrator and module. The clients represent the all possible suppliers of the air waste. Administrator should maintain the software through the process and modules should determine the optimal treatment and transport route of the air waste.

The main goals of the investigation is to decrease the emissions of the greenhouse gasses and generally to decrease global warming and pollution. Also biofuels need to be introduced in the transport as much as it can. The main activity of the investigation should be to develop the GPS system for mapping of the air waste suppliers in order to optimize the transport route.

Object-orientated modeling concepts are used during analyzing and modeling of the air waste management process. Two UML concepts are used for the software modeling like use case models, activity diagrams and scenarios of activities.

Software for Route Optimization for Waste Cooking Oil Transport

Software for route optimization for waste cooking oil transport should be use for organization of the waste cooking oil suppliers and collectors as well. The main advantage of the software for route optimization for waste cooking oil transport in the article is in its universality and in its online usage.

The main feature of the software for route optimization for waste cooking oil transport should be universal application for any subjects and any suppliers and collectors. The software for route optimization for waste cooking oil transport will be framework of the suppliers and collectors of the transport activity.

As users are considered suppliers in different parts of industry and collectors as well. All of the users should have username and password in order to access the waste cooking oil management database.

Collectors should made reports for different statistical analysis of the waste cooking oil. As the main problem of the current software for route optimization for waste cooking oil transport it was identified limitation of unified approach for all subjects. Therefore it is required to develop information system which would allow to users to use the software anytime in order to enter desired data.

Software users

The software users could be divided based on natural basis according to working place, suppliers and collectors. All of the users have equal rights to access and use of the software. Therefore the main users of the software are:

- Client,
- Module,
- Administrator.

Each of the users should have individual username and password in order to access to the software. Administrator of information system who needs to maintain the software and he is responsible for working of computer system and software as well. He gives permission to the staff's access to the waste cooking oil management database, maintains database, maintains web presentation of the waste cooking oil management and makes regular daily reports.

Software Analyzing

Each of the client should have individual username and password to access to the software. Administrator of software should maintain the software and he is responsible for working of computer system and software as well. He gives permission to the access to the database, maintains database, maintains web presentation of the software and makes regular daily reports.

Main use cases diagram of the software

Air waste treatment are depicted by the main use case diagram as it shown in Fig. 2. The main use case diagram has several sub use cases which will be explained in detail. As can be seen, the administrator should perform the main administration process of the air waste treatment in order to ensure smooth working processes by the software. Clients or suppliers record the quantity and composition of the air waste if they are logged in the software database. Based on the records the modules should determine the type of the air waster treatment.

Air waste transport are depicted by the main use case diagram as it shown in Fig. 3. Clients or suppliers record the coordinated of the air waste if they are logged in the software database. Based on the records the modules should determine the optimal route of air waste transport.

Use cases of the software subsystems

Software administration

Administrator performs software administration in order to eliminate all unpredictable errors in the software and system. Administrator has full responsibility for the software maintenance. They will give permissions for other users access to the system, maintains the software, maintains the web pages of the software, maintains the software database, and makes regular daily reports.

Fig. 2 Main use case diagram of the software for determining of air waste type treatment.

Fig. 3 Main use case diagram of the software for determining of optimal route of air waste transport.

Table 1 shows detailed specification of use case for giving permission for database access of the software by administrator.

Table 2 shows detailed specification of the use case of software maintaining by administrator.

Table 3 shows detailed specification of use case for web pages maintaining of software by administrator.

Table 4 shows detailed specification of use case for database maintaining of software by administrator.

Table 5 shows detailed specification of use case for making of regular reports by administrator.

Table 1 Specification of use case: Giving permission for database access

<i>Title</i>	<i>Giving permission for database access</i>
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the giving permission for database access.
Pre-condition	PC is properly settled. Administrator has needed knowledge for the tasks.
Post-condition	Client received authorization for database access of software
Main scenario	1. Administrator receives the request for the giving permission for database access of software. 2. Administrator checks the request validity. 3. Administrator fills the application form for the giving permission for database access of software. 4. Administrator selects client category based on the quantity of the waste cooking oil. 5. Administrator approves the request. 6. Administrator prints the instruction for the application use. 7. Administrator distributes the instruction to the client as the proof for the successful addition to the users of the waste cooking oil management software for the database access.
Alternative	1. In the case if the request is incorrect filled based on the step 2 of the main scenario the administrator returns the request to the client with the instruction how to correct the errors in the request.

Table 2 Specification of use case: Software maintaining

<i>Title</i>	<i>Software maintaining</i>
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the software maintaining.
Pre-condition	PC is properly settled. Administrator has needed knowledge for the tasks.
Post-condition	Backup of the waste cooking oil management software was made.
Main scenario	1. Administrator checks if there is some large operation on the software. 2. If there is some operation on the software, the administrator waits until the operation ends. 3. If there is not operation on the software, the administrator prepares tools for the software maintaining. 4. Administrator checks if the all functions of the software are proper. 5. Recording of composition of air waste

Use case recording of composition of air waste is depicted in Fig. 5. The use case diagram has several sub use cases. Table 6 shows detailed specification for use case recording of composition of air waste (Table 7).

Conclusion

Air waste management presents a big issue for all countries. One of the most common air waste treatment method is disposal. Illegal air waste disposal and unofficial air waste recycling could produce high pollution of water, air and soil. There is need for systematic sustainable air waste management system in order to preserve natural resources and to keep clean the life environment.

The main innovation of the investigation is analyzing and modeling of new software for air waste treatment. The main suppliers could enter quantity and composition of air waste in the software. Based on the quantity and composition the clients could decide which treatment and transport route is the best for the air waste they collected.

Modeling of Information System for Liquid Waste Management

Dalibor Petković, University of Niš, Pedagogical Faculty in Vranje, Partizanska, Vranje, Serbia

© 2020 Elsevier Inc. All rights reserved.

Introduction

The increasing trend in the consumption of various materials has also led to a huge increase in the liquid waste and the consequent environmental pollutions in particular greenhouse gas emissions. These have made liquid waste management a significant environmental issue for governments and policy-makers. To address these challenges, developed countries have implemented sustainable material management strategies which have been comprehensively reviewed herein. However, there is need to integrate the strategies in one information system for easy application.

An integrated system for waste reduction, collection, composting, recycling, and disposal is required to tackle the growing challenge of liquid waste management. Integrated liquid waste management involves many executive, operational and managerial decisions such as the siting of waste processing and disposal units, selection of waste-treatment technologies and allocation of waste flow to processing facilities and landfills.

Waste management process could be very complex task because of many different suppliers and collectors. There is need to make optimal route for the most efficient transport of the waste to the collectors. The main problem is suppliers motivation for such a process since they require simple and understandable process for the waste cooking oil management. Because of that it is suitable for the waste transport to model an software which will make more motivation for suppliers and collectors to make stronger and more uniform connections. The software could determine the optimal routes and treatments for the waste based on locations of suppliers. In this article object orientated approach is used for the software modeling (Lethbridge and Laganieri, 2005; Jacobson, 1993).

Object-orientated modeling strategy is an attempt to encapsulate data and process into thing called objects. The data in the objects could be created, deleted or used only by some encapsulated processes or methods. Unified modeling language (ULM) is a standard tool for object orientated modeling which could help to developers and engineers to make detailed specification and documentation of any system.

ULM (Rumbaugh *et al.*, 2004) is a graphical language which is effective for visualization, specification, construction and documentation of a system's artifact which is software intensive. ULM has standard practices for writing a blueprint of system. By using ULM one can cover various conceptual things such as functionality by use cases and business processes.

Modeling and analyzing of various activities in any system by ULM can help to visualize, specify, constructs and document the system artifact effectively which is helpful for better understanding of the problem and for various stakeholders of the application of the liquid waste management.

Literature Overview of Liquid Waste Management

In the article (Robertson *et al.*, 1987) was presented methods of disposal of today's hazardous household chemicals in the United States are frequently not acceptable because of pathways to groundwater, surface water, and the atmosphere and it was identified potentially hazardous liquid waste in the household, notes current disposal practices, and recommends an improved management plan that utilizes consumer education, manufacturer cooperation, and governmental intervention. Managing hazardous household wastes could mitigate potential disposal problems (Robertson *et al.*, 1987). In paper Pires and Martinho (2013) was compared 16 waste lubricant oil (WLO) systems (15 management alternatives and a system in use in Portugal) using a life cycle assessment (LCA). The results shown that mild processing with low liquid gas fuel consumption and re-refining is the best option to manage WLO with regard to abiotic depletion, eutrophication, global warming, and human toxicity environmental impacts (Pires and Martinho, 2013). In study Glazer *et al.* (2017) was compiled and curated data from 2012, 2013, and 2014 on flared gas and generated wastewater associated with hydraulic fracturing operations in seven major shale regions of the USA. In the process, an historical perspective was provided of the management practices of flared gas and wastewater prior to the decline in oil prices in 2015. The seven shale regions were evaluated using mass balances and thermodynamic analysis of the wastewater and flared gas volumes using data compiled from state, federal, and private sources for each region. The findings indicate that novel approaches to managing existing resources and waste streams might have the potential to improve the environmental footprint and economic productivity of select oil and gas sites (Glazer *et al.*, 2017). Marinas are usually located in coastal waters, but can also be found in lakes and rivers. Due to the activities that take place in marinas various contaminants are discharged. Specific measures have to be taken in order to keep the marina environment clean and healthy. Experiences from developed countries have shown that the most effective way to reduce pollution in marinas is the implementation of waste management programs (Dolgen *et al.*, 2003). In article (Dolgen *et al.*, 2003) the importance of management programs towards the mitigation of pollution problems was emphasized. The radiation contamination after the Fukushima Daiichi Nuclear Power Plant accident attracts considerable concern all over the world. Many countries, areas, and oceans are greatly affected by the emergency situation other than Japan. An effective remediation strategy is in a highly urgent demand (Ding *et al.*, 2016). The policy of establishing new universities across Taiwan has led to an

increase in the number of universities, and many schools have constructed new laboratories to meet students' academic needs. In recent years, there is an increase in the number of laboratory accidents from the liquid waste in universities (Ho and Chen, 2018). Therefore, how to build a safety system for laboratory liquid waste disposal has become an important issue in the environmental protection, safety, and hygiene of all universities. In study Ikhlayel (2017) was aimed to evaluate the environmental impacts and benefits of state-of-the-art technologies for proper e-waste handling using Jordan as a case study. Life Cycle Assessment (LCA) was employed to evaluate five advanced management systems represent state-of-the-art treatment technologies, including sanitary landfilling; proper recycling of metals, materials, and precious metals (PMs); and incineration of plastic and the hazardous portion of printed circuit boards (PCBs). The Liquid Waste Management System (LWMS) is a radioactive waste storage and treatment facility equipped in the nuclear power plants to ensure the safe management of radioactive waste generated in the process of operation (Kim and Kim, 2017). An optimization-based supply chain management framework for municipal liquid waste (MSW) to liquid transportation fuels (WTL) processes was presented in article (Niziolek *et al.*, 2017).

Materials and Methods

Liquid Waste Management

According to the European Union standardization there are six procedures in the liquid waste treatment process:

1. Eco-design,
2. Liquid waste decreasing,
3. Liquid waste reusing,
4. Recycling and making compost,
5. Energy from liquid waste,
6. Liquid waste disposing.

The main activity of the investigation is to develop two separate softwares in order to make sustainable liquid waste management. In order to optimize the system for liquid waste management based on decreasing of pollution of life environment and for the cheapest solution there is goal to develop and model the software for the liquid waste management process. This innovative solution could lead to revolution in the liquid waste issue. By entering of the main data for liquid waste, quantity and composition for the some region, the client could know which is the best solution for the liquid waste treatment and transport for the region. Several liquid waste treatments are included in the software:

- Recycling,
- Combusting,
- Making compost,
- Performing anaerobic digestion and
- Disposing of liquid waste.

There are several indicators which are calculated in the software according the input data. These indicators are:

- Global warming,
- Heavy metals emission,
- Nitrogen oxide emission,
- Smog formation,
- Water pollution.

Therefore these software has seven modules. These modules:

- Calculation of emissions from collection and transport of liquid waste,
- Calculation of emissions from anaerobic digestion,
- Calculation of emissions from combustion,
- Calculation of emissions from recycled waste,
- Calculation of emissions from disposal,
- Calculation of emissions from compost,
- Calculation of cost benefit.

There is also plan to integrate the module for determination of the optimal route of the liquid waste transport. The optimization of the route is very important since there is constantly changing of the urban parameters: Number of residents, waste quantity, type of transport vehicle, transport conditions. Clark and Wright savings algorithm could be applied for the route optimization for the liquid waste.

This software approach for the liquid waste management could be very helpful for managers who control waste, companies which produce and transport the waste and for decision makers to select the optimal scenery for the waste treatment and transport for each region. The main goals of the investigation are:

- Removing of the barriers for the decreasing of pollution of life environment by unsuitable treatment of the liquid waste.
- Increasing of ecological awareness for the importance of regular treatment of waste,
- Solving of problem of liquid waste collection and transport.

Specific goal of the investigation is:

- Modeling of innovative software as a tool for determination of a right strategy for liquid waste management.

Software Development for Liquid Waste Management

Generally, the software development methodology is consisted of procedures, technics, tools and documentation which helps in the software development process. Software development methodology describes all steps and phases of the software development. The methodology suggest tools and technics which should use in the particular step of the software development. Also the methodology could suggest how to plan and track process of the software development and testing as well.

Many companies use the methodologies for software development in order to ensure the consistency of the problem solution, to decrease the possible errors, to acquire the full documentation for current and future projects and to get good final product which could be changeable and adaptable easily since the all steps and phases would be documented in detail and any new changes in the software models could be achieved before software coding.

Models could be describes as simplified presentation of reality. The models could be presented with some standard modeling language. The model presentation could be textual or graphical by diagrams. Each software could be described based on different aspects by structural models in order to show software structure with the main parts and their interconnections and relationships. Also there is behaviour models where one can track the software dynamics.

RUP methodology

Rational Unified Process (RUP) is an interactive methodology for the software development based on architecture and use cases. RUP methodology is based on Unified Modeling Language (UML). UML is used for specification, visualization, construction and documentation of the software development.

RUP methodology has control, key or critical points through the development. In the other words each phase of the RUP methodology should end by some control, key or critical points where achieved results are summed and future directions are planned based on the results. RUP methodology has artifacts (documents), models and model elements. Project requests are noted in the documents. Models are used to simplify the software architecture without unnecessary details. Model elements could help to visualize, construct and document the main structure and software behaviour.

RUP methodology has four main phases. The first phase is initial phase or idea inception where one needs to understand what should to do and software vision and requirements are identified. This phase includes the identification of key software actors (users) and use cases. Also there is need to identify software domain. Use case defines one sequence of an action which software performs that yields to an observable results. In the other hands one use case presents result of an action by actor (Fig. 1). Use case presents the main part of some complete software operation from beginning until to the end. It is used to capture the intended behaviour of the system in development. By use cases models desired behaviour of the system could be specified but it is not strictly this desired behaviour to be carried out or implemented in the final product. Use cases models can be developed for whole system or for the part of system. Each part of system or subsystem can be developed by use cases models until the part produces some tangible amount of work and results. System complexity indicates the number of use cases. In the initial stage of system development main use cases are developed and additional use cases can be added or included when there is need for them.

The second phase is project elaboration where one needs to understand how to build the software and basic software architecture is showed in the phase. The third phase presents software construction where software testing is considered. The fourth phase presents software transition where software validation is performed.

RUP models describes software in modeling. RUP models could be business models which describes business processes and business environment, use case models which describes what software doing and software environment, projecting models which describes use cases realization as code abstraction and implementation models which presents collection of components and subsystems.

Software development process could has different problems which needs to be identifies and solved before coding and testing. In order to solve problems there is need to find the problem causes. To remove the problem causes it is suitable to use best

Fig. 1 Use case model.

practices. For example in order to remove the confusion in communication between team members it is suitable to use standard language UML for the software visualization, specification and documentation. There are different types of UML diagrams which can be used in the software development process. There are two main classes of the UML diagrams. These are structural and behavioral diagrams. Structural diagram presents structure of the system in passive state and behavioral diagram present the active behaviour of the objects in a system or dynamical state.

Object-orientated modeling of business process

UML is used for object-orientated modeling of business process. As already mentioned there are different UML diagrams for describing of software architecture and software behaviour. UML as standard language is used for modeling, for analyzing, for projecting and for implementation of the software system. Based on the object-orientated modeling all process could be presented by use cases models as rough specification and by structural diagrams and behavioral diagrams as detail specification.

During modeling of the business process it is not recommended to use natural language because of its ambiguity. Also formal programming languages is not understandable for many people in the project team. Therefore it is suitable to organize the natural language to avoid ambiguity. Modeling process is one of the solution for understanding and clear communication between project team members.

Modeling of the Liquid Waste Management

Problem Description

The problem is intended for solving of treatment and transport of liquid waste. The main objects of the model are clients, administrator and modula. The clients represent the all possible suppliers of the liquid waste. Administrator should maintain the software through the process and modules should determine the optimal treatment and transport route of the liquid waste.

Fig. 2 Main use case diagram of the software for determining of liquid waste type treatment.

Fig. 3 Main use case diagram of the software for determining of optimal route of liquid waste transport.

Table 1 Specification of use case: Giving permission for database access

Title	Giving permission for database access
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the giving permission for database access
Pre-condition	PC is properly settled Administrator has needed knowledge for the tasks
Post-condition	Client received authorization for database access of software
Main scenario	1. Administrator receives the request for the giving permission for database access of software 2. Administrator checks the request validity 3. Administrator fills the application form for the giving permission for database access of software 4. Administrator selects client category based on the quantity of the waste cooking oil 5. Administrator approves the request 6. Administrator prints the instruction for the application use 7. Administrator distributes the instruction to the client as the proof for the successful addition to the users of the waste cooking oil management software for the database access
Alternative	1. In the case if the request is incorrect filled based on the step 2. of the main scenario the administrator returns the request to the client with the instruction how to correct the errors in the request

The main goals of the investigation is to decrease the emissions of the greenhouse gasses and generally to decrease global warming and pollution. Also biofuels need to be introduced in the transport as much as it can. The main activity of the investigation should be to develop the GPS system for mapping of the liquid waste suppliers in order to optimize the transport route.

Object-oriented modeling concepts are used during analyzing and modeling of the liquid waste management process. Two UML concepts are used for the software modeling like use case models, activity diagrams and scenarios of activities.

Software for Route Optimization for Waste Cooking Oil Transport

Software for route optimization for waste cooking oil transport should be use for organization of the waste cooking oil suppliers and collectors as well. The main advantage of the software for route optimization for waste cooking oil transport in the article is in its universality and in its online usage.

The main feature of the software for route optimization for waste cooking oil transport should be universal application for any subjects and any suppliers and collectors. The software for route optimization for waste cooking oil transport will be framework of the suppliers and collectors of the transport activity.

As users are considered suppliers in different parts of industry and collectors as well. All of the users should have username and password in order to access the waste cooking oil management database.

Collectors should made reports for different statistical analysis of the waste cooking oil. As the main problem of the current software for route optimization for waste cooking oil transport it was identified limitation of unified approach for all subjects. Therefore it is required to develop information system which would allow to users to use the software anytime in order to enter desired data.

Software users

The software users could be divided based on natural basis according to working place, suppliers and collectors. All of the users have equal rights to access and use of the software. Therefore the main users of the software are:

- Client,
- Module,
- Administrator.

Each of the users should have individual username and password in order to access to the software. Administrator of information system who needs to maintain the software and he is responsible for working of computer system and software as well. He

gives permission to the staff's access to the waste cooking oil management database, maintains database, maintains web presentation of the waste cooking oil management and makes regular daily reports.

Software Analyzing

Each of the client should have individual username and password to access to the software. Administrator of software should maintain the software and he is responsible for working of computer system and software as well. He gives permission to the access to the database, maintains database, maintains web presentation of the software and makes regular daily reports.

Main use cases diagram of the software

Liquid waste treatment are depicted by the main use case diagram as it shown in [Fig. 2](#). The main use case diagram has several sub use cases which will be explained in detail. As can be seen, the administrator should perform the main administration process of the liquid waste treatment in order to ensure smooth working processes by the software. Clients or suppliers record the quantity and composition of the liquid waste if they are logged in the software database. Based on the records the modules should determine the type of the liquid waster treatment.

Liquid waste transport are depicted by the main use case diagram as it shown in [Fig. 3](#). Clients or suppliers record the coordinated of the liquid waste if they are logged in the software database. Based on the records the modules should determine the optimal route of liquid waste transport.

Introduction

The increasing trend in the consumption of various materials has also led to a huge increase in the nuclear waste and the consequent environmental pollutions in particular greenhouse gas emissions. These have made nuclear waste management a significant environmental issue for governments and policy-makers. To address these challenges, developed countries have implemented sustainable material management strategies which have been comprehensively reviewed herein. However, there is need to integrate the strategies in one information system for easy application.

An integrated system for waste reduction, collection, composting, recycling, and disposal is required to tackle the growing challenge of nuclear waste management. Integrated nuclear waste management involves many executive, operational and managerial decisions such as the siting of waste processing and disposal units, selection of waste-treatment technologies and allocation of waste flow to processing facilities and landfills.

Waste management process could be very complex task because of many different suppliers and collectors. Suppliers could be industrial buildings which produce large masses of nuclear waste and collectors should reduce the nuclear waste. There is need to make optimal route for the most efficient transport of the waste to the collectors. In other word there is need to find the most efficient way to detect and decrease the nuclear waste. The main problem is suppliers motivation for such a process since they require simple and understandable process for the nuclear waste management. It is suitable to model an software which will make more motivation for suppliers and collectors to make stronger and more uniform connections. The software could determine the optimal routes and treatments for the waste based on locations of suppliers. In this article object orientated approach is used for the software modeling (Lethbridge and Laganieri, 2005; Jacobson, 1993).

Object-orientated modeling strategy is an attempt to encapsulate data and process into thing called objects. The data in the objects could be created, deleted or used only by some encapsulated processes or methods. Unified modeling language (UML) is a standard tool for object orientated modeling which could help to developers and engineers to make detailed specification and documentation of any system.

UML (Rumbaugh *et al.*, 2004) is a graphical language which is effective for visualization, specification, construction and documentation of a system's artifact which is software intensive. UML has standard practices for writing a blueprint of system. By using UML one can cover various conceptual things such as functionality by use cases and business processes.

Modeling and analyzing of various activities in any system by UML can help to visualize, specify, constructs and document the system artifact effectively which is helpful for better understanding of the problem and for various stakeholders of the application of the nuclear waste management.

Materials and Methods

Nuclear Waste Management

According to the European Union standardization there are six procedures in the nuclear waste treatment process:

1. Eco-design,
2. Nuclear waste decreasing,
3. Nuclear waste reusing,
4. Recycling and making compost,
5. Energy from nuclear waste,
6. Nuclear waste disposing.

The main activity of the investigation is to develop two separate softwares in order to make sustainable nuclear waste management. In order to optimize the system for nuclear waste management based on decreasing of pollution of life environment and for the cheapest solution there is goal to develop and model the software for the nuclear waste management process. This innovative solution could lead to revolution in the nuclear waste issue. By entering of the main data for nuclear waste, quantity and composition for the some region, the client could know which is the best solution for the nuclear waste treatment and transport for the region. Several nuclear waste treatments are included in the software:

- Recycling,
- Combusting,
- Making compost,
- Performing anaerobic digestion and
- Disposing of nuclear waste.

There are several indicators which are calculated in the software according the input data. These indicators are:

- Global warming,
- Heavy metals emission,
- Nitrogen oxide emission,
- Smog formation,
- Water pollution.

Therefore these software has seven modules. These modules

- Calculation of emissions from collection and transport of nuclear waste,
- Calculation of emissions from anaerobic digestion,
- Calculation of emissions from combustion,
- Calculation of emissions from recycled waste,
- Calculation of emissions from disposal,
- Calculation of emissions from compost,
- Calculation of cost benefit.

There is also plan to integrate the module for determination of the optimal route of the nuclear waste transport. The optimization of the route is very important since there is constantly changing of the urban parameters: number of residents, waste quantity, type of transport vehicle, transport conditions. Clark and Wright savings algorithm could be applied for the route optimization for the nuclear waste.

This software approach for the nuclear waste management could be very helpful for managers who control waste, companies which produce and transport the waste and for decision makers to select the optimal scenery for the waste treatment and transport for each region. The main goals of the investigation are:

- Removing of the barriers for the decreasing of pollution of life environment by nonsuitable treatment of the nuclear waste.
- Increasing of ecological awareness for the importance of regular treatment of waste.
- Solving of problem of nuclear waste collection and transport.

Specific goal of the investigation is:

- Modeling of innovative software as a tool for determination of a right strategy for nuclear waste management.

Software Development for Nuclear Waste Management

Generally, the software development methodology is consisted of procedures, technics, tools and documentation which helps in the software development process. Software development methodology describes all steps and phases of the software development. The methodology suggest tools and technics which should use in the particular step of the software development. Also the methodology could suggest how to plan and track process of the software development and testing as well.

Many companies use the methodologies for software development in order to ensure the consistency of the problem solution, to decrease the possible errors, to acquire the full documentation for current and future projects and to get good final product which could be changeable and adaptable easily since the all steps and phases would be documented in detail and any new changes in the software models could be achieved before software coding.

Models could be describes as simplified presentation of reality. The models could be presented with some standard modeling language. The model presentation could be textual or graphical by diagrams. Each software could be described based on different aspects by structural models in order to show software structure with the main parts and their interconnections and relationships. Also there is behaviour models where one can track the software dynamics.

RUP methodology

Rational Unified Process (RUP) is an iterative methodology for the software development based on architecture and use cases. RUP methodology is based on Unified Modeling Language (UML). UML is used for specification, visualization, construction and documentation of the software development.

RUP methodology has control, key or critical points through the development. In the other words each phase of the RUP methodology should end by some control, key or critical points where achieved results are summed and future directions are planned based on the results. RUP methodology has artefacts (documents), models and model elements. Project requests are noted in the documents. Models are used to simplify the software architecture without unnecessary details. Model elements could help to visualize, construct and document the main structure and software behaviour.

RUP methodology has four main phases. The first phase is initial phase or idea inception where one needs to understand what should to do and software vision and requirements are identified. This phase includes the identification of key software actors (users) and use cases. Also there is need to identify software domain. Use case defines one sequence of an action which software performs that yields to an observable results. In the other hands one use case presents result of an action by actor. Use case presents the main part of some complete software operation from beginning until to the end. It is used to capture the intended behaviour

of the system in development. By use cases models desired behaviour of the system could be specified but it is not strictly this desired behaviour to be carried out or implemented in the final product. Use cases models can be developed for whole system or for the part of system. Each part of system or subsystem can be developed by use cases models until the part produces some tangible amount of work and results. System complexity indicates the number of use cases. In the initial stage of system development main use cases are developed and additional use cases can be added or included when there is need for them.

The second phase is project elaboration where one needs to understand how to build the software and basic software architecture is showed in the phase. The third phase presents software construction where software testing is considered. The fourth phase presents software transition where software validation is performed.

RUP models describes software in modeling. RUP models could be business models which describes business processes and business environment, use case models which describes what software doing and software environment, projecting models which describes use cases realization as code abstraction and implementation models which presents collection of components and subsystems.

Software development process could has different problems which needs to be identifies and solved before coding and testing. In order to solve problems there is need to find the problem causes. To remove the problem cause it is suitable to use best practices. For example in order to remove the confusion in communication between team members it is suitable to use standard language UML for the software visualization, specification and documentation. There are different types of UML diagrams which can be used in the software development process. There are two main classes of the UML diagrams. These are structural and behavioral diagrams. Structural diagram presents structure of the system in passive state and behavioral diagram present the active behaviour of the objects in a system or dynamical state.

Object-orientated modeling of business process

UML is used for object-orientated modeling of business process. As already mentioned there are different UML diagrams for describing of software architecture and software behaviour. UML as standard language is used for modeling, for analyzing, for projecting and for implementation of the software system. Based on the object-orientated modeling all process could be presented by use cases models as rough specification and by structural diagrams and behavioral diagrams as detail specification.

During modeling of the business process it is not recommended to use natural language because of its ambiguity. Also formal programming languages is not understandable for many people in the project team. Therefore it is suitable to organize the natural language to avoid ambiguity. Modeling process is one of the solution for understanding and clear communication between project team members.

Modeling of the Nuclear Waste Management

Problem Description

The problem is intended for solving of treatment and transport of nuclear waste. The main objects of the model are clients, administrator and modula. The clients represent the all possible suppliers of the nuclear waste. Administrator should maintain the software through the process and modules should determine the optimal treatment and transport route of the nuclear waste.

The main goals of the investigation is to decrease the emissions of the greenhouse gasses and generally to decrease global warming and pollution. Also biofuels need to be introduced in the transport as much as it can. The main activity of the investigation should be to develop the GPS system for mapping of the nuclear waste suppliers in order to optimize the transport route.

Object-oriented modeling concepts are used during analyzing and modeling of the nuclear waste management process. Two UML concepts are used for the software modeling like use case models, activity diagrams and scenarios of activities.

Software for Route Optimization for Waste Nuclear Transport

Software for route optimization for waste cooking oil transport should be use for organization of the waste cooking oil suppliers and collectors as well. The main advantage of the software for route optimization for waste cooking oil transport in the article is in its universality and in its online usage.

The main feature of the software for route optimization for waste cooking oil transport should be universal application for any subjects and any suppliers and collectors. The software for route optimization for waste cooking oil transport will be framework of the suppliers and collectors of the transport activity.

As users are considered suppliers in different parts of industry and collectors as well. All of the users should have username and password in order to access the waste cooking oil management database.

Collectors should made reports for different statistical analysis of the waste cooking oil. As the main problem of the current software for route optimization for waste cooking oil transport it was identified limitation of unified approach for all subjects. Therefore it is required to develop information system which would allow to users to use the software anytime in order to enter desired data.

Software users

The software users could be divided based on natural basis according to working place, suppliers and collectors. All of the users have equal rights to access and use of the software. Therefore the main users of the software are:

- Client,
- Module,
- Administrator.

Each of the users should have individual username and password in order to access to the software. Administrator of information system who needs to maintain the software and he is responsible for working of computer system and software as well. He gives permission to the staff's access to the waste cooking oil management database, maintains database, maintains web presentation of the waste cooking oil management and makes regular daily reports.

Software Analyzing

Each of the client should have individual username and password to access to the software. Administrator of software should maintain the software and he is responsible for working of computer system and software as well. He gives permission to the access to the database, maintains database, maintains web presentation of the software and makes regular daily reports.

Main use cases diagram of the software

Nuclear waste treatment are depicted by the main use case diagram as it shown in Fig. 1. The main use case diagram has several sub use cases which will be explained in detail. As can be seen, the administrator should perform the main administration process of the nuclear waste treatment in order to ensure smooth working processes by the software. Clients or suppliers record the quantity and composition of the nuclear waste if they are logged in the software database. Based on the records the modules should determine the type of the nuclear waster treatment.

Nuclear waste transport are depicted by the main use case diagram as it shown in Fig. 2. Clients or suppliers record the coordinated of the nuclear waste if they are logged in the software database. Based on the records the modules should determine the optimal route of nuclear waste transport.

Fig. 1 Main use case diagram of the software for determining of nuclear waste type treatment.

Fig. 2 Main use case diagram of the software for determining of optimal route of nuclear waste transport.

Fig. 3 Use case diagram – Recording of quantity of nuclear waste.

Use cases of the software subsystems

Software administration

Administrator performs software administration in order to eliminate all unpredictable errors in the software and system. Administrator has full responsibility for the software maintenance. They will give permissions for other users access to the system, maintains the software, maintains the web pages of the software, maintains the software database, and makes regular daily reports.

Recording of quantity of nuclear waste

Use case recording of quantity of nuclear waste is depicted in [Fig. 3](#). The use case diagram has several sub use cases. [Table 1](#) shows detailed specification for use case recording of quantity of nuclear waste.

Table 1 Specification of use case: Recording of quantity of nuclear waste

Title	Recording of quantity of nuclear waste
Actors	Client
Trigger	It starts with the choosing of the option on user interface for the recording of quantity of nuclear waste
Pre-condition	PC is properly settled. Nuclear waste acquired.
Post-condition	Recorded quantity of nuclear waste.
Main scenario	1. Client starts nuclear waste management software. 2. Client does login into nuclear waste management software. 3. Client records the quantity of nuclear waste. 4. Client confirms the quantity.
Alternative	1. The recording of quantity of nuclear waste is canceled. 2. Due to technical problems the service cannot be made.

**Fig. 4** Use case diagram – Recording of composition of nuclear waste.**Table 2** Specification of use case: Recording of composition of nuclear waste

Title	Recording of composition of nuclear waste
Actors	Client
Trigger	It starts with the choosing of the option on user interface for the recording of composition of nuclear waste
Pre-condition	PC is properly settled. Nuclear waste acquired.
Post-condition	Recorded composition of nuclear waste.
Main scenario	1. Client starts nuclear waste management software. 2. Client does login into nuclear waste management software. 3. Client records the composition of nuclear waste. 4. Client confirms the composition.
Alternative	1. The recording of composition of nuclear waste is canceled. 2. Due to technical problems the service cannot be made.

Recording of composition of nuclear waste

Use case recording of composition of nuclear waste is depicted in [Fig. 4](#). The use case diagram has several sub use cases. [Table 2](#) shows detailed specification for use case recording of composition of nuclear waste.

Conclusion

Nuclear waste management present a big issue for all countries. One of the most common nuclear waste treatment method is disposal. Illegal nuclear waste disposal and inofficial nuclear waste recycling could produce high pollution of water, nuclear and soil. There is need for systematic sustainable nuclear waste management system in order to preserve natural resources and to keep clean the life environment.

The main innovation of the investigation is analyzing and modeling of new software for nuclear waste treatment. The main suppliers could enter quantity and composition of nuclear waste in the software. Based on the quantity and composition the clients could decide which treatment and transport route is the best for the nuclear waste they collected.

Introduction

The increasing trend in the consumption of various materials has also led to a huge increase in the solid waste and the consequent environmental pollutions in particular greenhouse gas emissions. These have made solid waste management a significant environmental issue for governments and policy-makers. To address these challenges, developed countries have implemented sustainable material management strategies which have been comprehensively reviewed herein. However, there is need to integrate the strategies in one information system for easy application.

An integrated system for waste reduction, collection, composting, recycling, and disposal is required to tackle the growing challenge of solid waste management. Integrated solid waste management involves many executive, operational and managerial decisions such as the siting of waste processing and disposal units, selection of waste-treatment technologies and allocation of waste flow to processing facilities and landfills.

Waste management process could be very complex task because of many different suppliers and collectors. There is need to make optimal route for the most efficient transport of the waste to the collectors. The main problem is suppliers motivation for such a process since they require simple and understandable process for the waste cooking oil management. Because of that it is suitable for the waste transport to model an software which will make more motivation for suppliers and collectors to make stronger and more uniform connections. The software could determine the optimal routes and treatments for the waste based on locations of suppliers. In this article object orientated approach is used for the software modeling (Lethbridge and Laganiere, 2005; Jacobson, 1993).

Object-orientated modeling strategy is an attempt to encapsulate data and process into thing called objects. The data in the objects could be created, deleted or used only by some encapsulated processes or methods. Unified modeling language (ULM) is a standard tool for object orientated modeling which could help to developers and engineers to make detailed specification and documentation of any system.

ULM (Rumbaugh *et al.*, 2004) is a graphical language which is effective for visualization, specification, construction and documentation of a system's artifact which is software intensive. ULM has standard practices for writing a blueprint of system. By using ULM one can cover various conceptual things such as functionality by use cases and business processes.

Modeling and analyzing of various activities in any system by ULM can help to visualize, specify, constructs and document the system artifact effectively which is helpful for better understanding of the problem and for various stakeholders of the application of the solid waste management.

Literature Overview

A lack of attention to the role of urbanites in municipal solid waste management (MSWM) has contributed to poor state of solid waste management (SWM) (Cobbina *et al.*, 2017). In study (Maalouf and El-Fadel, 2017), the carbon footprint of introducing a food waste disposer (FWD) policy was examined in the context of its implications on solid waste and the sensitivity analyses on processes with a wide range in costs showed an equivalent economic impact thus emphasizing the viability of a FWD policy although the variation in the cost of sludge management exhibited a significant impact on savings. Waste characterization is the first step to any successful waste management policy (Adeniran *et al.*, 2017). Informal waste recycling has become an important activity in the urban regions. Using empirical data collected through the tradition of participatory research, the findings suggest that waste pickers play a vital role in municipal solid waste management and make a significant contribution to the city's economic growth as well as environmental wellness (Simatele *et al.*, 2017). Currently, the overwhelming majority of municipal solid waste (MSW) has been treated in sanitary landfills and incineration plants. In future, with the popularization of separate waste collection, it is logical to treat the biodegradable components using biological treatment technologies (Liu *et al.*, 2017b). Contracting out local solid waste management service is assumed to deliver cost savings without sacrificing the service quality (Zhu and Huang, 2017). The paper (Rajaeifar *et al.*, 2017) was aimed at comprehensively assessing electricity generation potentials from MSW using an integrated solid waste management system (including three different technologies of anaerobic digestion (AD), incineration, and pyrolysis-gasification) while the consequent greenhouse gases emission reduction potentials as a result of their implementation were also explored. In study (Asefi and Lim, 2017) was aimed to satisfy the sustainability requirements for designing an ISWM system by taking economic, environmental and social factors into account. The study (Kumar and Samadder, 2017) was reviewed the current global scenario of waste to energy (WTE) technological options (incineration, pyrolysis, gasification, anaerobic digestion, and landfilling with gas recovery) for effective energy recovery and the challenges faced by developed and developing countries. Ecological-economic evaluation of different treatment technologies is to achieve the maximum practical benefits from investments and to ensure the minimum environmental impacts of waste flows based on variable source-separated collection

and transportation rates were analyzed in paper (Liu *et al.*, 2017a). Municipal solid waste treatment options are not necessarily pragmatic if the stakeholders in the system don't mutually agree on their shares of liabilities (Soltani *et al.*, 2017). With the booming economy and increasing population, the accumulation of waste has become an increasingly arduous issue and has aroused the attention from all sectors of society (Lee *et al.*, 2016).

Materials and Methods

Solid Waste Management

According to the European Union standardization there are six procedures in the solid waste treatment process:

1. Eco-design,
2. Solid waste decreasing,
3. Solid waste reusing,
4. Recycling and making compost,
5. Energy from solid waste,
6. Solid waste disposing.

The main activity of the investigation is to develop two separate softwares in order to make sustainable solid waste management. In order to optimize the system for solid waste management based on decreasing of pollution of life environment and for the cheapest solution there is goal to develop and model the software for the solid waste management process. This innovative solution could lead to revolution in the solid waste issue. By entering of the main data for solid waste, quantity and composition for the some region, the client could know which is the best solution for the solid waste treatment and transport for the region. Several solid waste treatments are included in the software:

- Recycling,
- Combusting,
- Making compost,
- Performing anaerobic digestion, and
- Disposing of solid waste.

There are several indicators which are calculated in the software according the input data. These indicators are:

- Global warming,
- Heavy metals emission,
- Nitrogen oxide emission,
- Smog formation,
- Water pollution.

Therefore these software has seven modules. These modules

- Calculation of emissions from collection and transport of solid waste,
- Calculation of emissions from anaerobic digestion,
- Calculation of emissions from combustion,
- Calculation of emissions from recycled waste,
- Calculation of emissions from disposal,
- Calculation of emissions from compost,
- Calculation of cost benefit.

There is also plan to integrate the module for determination of the optimal route of the solid waste transport. The optimization of the route is very important since there is constantly changing of the urban parameters: number of residents, waste quantity, type of transport vehicle, transport conditions. Clark and Wright savings algorithm could be applied for the route optimization for the solid waste.

This software approach for the solid waste management could be very helpful for managers who control waste, companies which produce and transport the waste and for decision makers to select the optimal scenery for the waste treatment and transport for each region. The main goals of the investigation are:

- Removing of the barriers for the decreasing of pollution of life environment by nonsuitable treatment of the solid waste,
- Increasing of ecological awareness for the importance of regular treatment of waste,
- Solving of problem of solid waste collection and transport.

Specific goal of the investigation is:

- Modeling of innovative software as a tool for determination of a right strategy for solid waste management.

Software Development for Solid Waste Management

Generally, the software development methodology is consisted of procedures, technique, tools and documentation which helps in the software development process. Software development methodology describes all steps and phases of the software development. The methodology suggest tools and technics which should use in the particular step of the software development. Also the methodology could suggest how to plan and track process of the software development and testing as well.

Many companies use the methodologies for software development in order to ensure the consistency of the problem solution, to decrease the possible errors, to acquire the full documentation for current and future projects and to get good final product which could be changeable and adaptable easily since the all steps and phases would be documented in detail and any new changes in the software models could be achieved before software coding.

Models could be describes as simplified presentation of reality. The models could be presented with some standard modeling language. The model presentation could be textual or graphical by diagrams. Each software could be described based on different aspects by structural models in order to show software structure with the main parts and their interconnections and relationships. Also there is behavior models where one can track the software dynamics.

RUP methodology

Rational Unified Process (RUP) is an interactive methodology for the software development based on architecture and use cases. RUP methodology is based on Unified Modeling Language (UML). UML is used for specification, visualization, construction and documentation of the software development.

RUP methodology has control, key or critical points through the development. In the other words each phase of the RUP methodology should end by some control, key or critical points where achieved results are summed and future directions are planned based on the results. RUP methodology has artifacts (documents), models i model elements. Project requests are noted in the documents. Models are used to simplify the software architecture without unnecessary details. Model elements could help to visualize, construct and document the main structure and software behavior. Fig. 1 shows the main elements of the RUP methodology. Each phase of the RUP methodology has iteration where disciplines are considered. The disciplines are described by process flow in details. The process shows activity and roles of everyone in the project. Finally there are artifacts where one can see software documentation, software models and model elements.

RUP methodology has four main phases. The first phase is initial phase or idea inception where one needs to understand what should to do and software vision and requirements are identified. This phase includes the identification of key software actors (users) and use cases. Also there is need to identify software domain. Use case defines one sequence of an action which software performs that yields to an observable results. In the other hands one use cases presents result of an action by actor (Fig. 2). Use case presents the main part of some complete software operation from beginning until to the end. It is used to capture the intended behavior of the system in development. By use cases models desired behavior of the system could be specified but it is not strictly this desired behavior to be carried out or implemented in the final product. Use cases models can be developed for whole system or for the part of system. Each part of system or subsystem can be developed by use cases models until the part produces some tangible amount of work and results. System complexity indicates the number of use cases. In the initial stage of system development main use cases are developed and additional use cases can be added or included when there is need for them.

The second phase is project elaboration where one needs to understand how to build the software and basic software architecture is showed in the phase. The third phase presents software construction where software testing is considered. The fourth phase presents software transition where software validation is performed. The RUP phases are shown in Fig. 3.

Fig. 1 Elements of RUP methodology.

Fig. 2 Use case model.

Fig. 3 RUP methodology phases.

Fig. 4 Main use case diagram of the software for determining of solid waste type treatment.

RUP models describes software in modeling. RUP models could be business models which describes business process and business environment, use case models which describes what software doing and software environment, projecting models which describes use cases realization as code abstraction and implementation models which presents collection of components and subsystems.

Software development process could has different problems which needs to be identifies and solved before coding and testing. In order to solve problems there is need to find the problem causes. To remove the problem causes it is suitable to use best practices. For example in order to remove the confusion in communication between team members it is suitable to use standard language UML for the software visualization, specification and documentation. There are different types of UML diagrams which can be used in the software development process. There are two main classes of the ULM diagrams. These are structural and behavioral diagrams. Structural diagram presents structure of the system in passive state and behavioral diagram present the active behavior of the objects in a system or dynamical state.

Object-orientated modeling of business process

UML is used for object-orientated modeling of business process. As already mentioned there are different UML diagrams for describing of software architecture and software behavior. UML as standard language is used for modeling, for analyzing, for projecting and for implementation of the software system. Based on the object-orientated modeling all process could be presented by use cases models as rough specification and by structural diagrams and behavioral diagrams as detail specification.

During modeling of the business process it is not recommended to use natural language because of its ambiguity. Also formal programming languages is not understandable for many people in the project team. Therefore it is suitable to organize the natural language to avoid ambiguity. Modeling process is one of the solution for understanding and clear communication between project team members.

Modeling of the Solid Waste Management

Problem Description

The problem is intended for solving of treatment and transport of solid waste. The main objects of the model are clients, administrator and modula. The clients represent the all possible suppliers of the solid waste. Administrator should maintain the software throughout the process and modules should determine the optimal treatment and transport route of the solid waste.

The main goals of the investigation is to decrease the emissions of the greenhouse gasses and generally to decrease global warming and pollution. Also biofuels need to be introduced in the transport as much as it can. The main activity of the investigation should be to develop the GPS system for mapping of the solid waste suppliers in order to optimize the transport route.

Object-orientated modeling concepts are used during analyzing and modeling of the solid waste management process. Two UML concepts are used for the software modeling like use case models, activity diagrams and scenarios of activities.

Software for Route Optimization for Waste Cooking Oil Transport

Software for route Optimization for waste cooking oil transport should be use for organization of the waste cooking oil suppliers and collectors as well. The main advantage of the software for route Optimization for waste cooking oil transport in the article is in its universality and in its online usage.

The main feature of the software for route Optimization for waste cooking oil transport should be universal application for any subjects and any suppliers and collectors. The software for route Optimization for waste cooking oil transport will be framework of the suppliers and collectors of the transport activity.

As users are considered suppliers in different parts of industry and collectors as well. All of the users should have username and password in order to access the waste cooking oil management database.

Collectors should made reports for different statistical analysis of the waste cooking oil. As the main problem of the current software for route Optimization for waste cooking oil transport it was identified limitation of unified approach for all

Fig. 5 Main use case diagram of the software for determining of optimal route of solid waste transport.

subjects. Therefore it is required to develop information system which would allow to users to use the software anytime in order to enter desired data.

Software users

The software users could be divided based on natural basis according to working place, suppliers and collectors. All of the users have equal rights to access and use of the software. Therefore the main users of the software are:

- Client,
- Module,
- Administrator.

Fig. 6 Use case diagram – Software administration.

Table 1 Specification of use case: Giving permission for database access

Title	Giving permission for database access
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the giving permission for database access
Pre-condition	PC is properly settled Administrator has needed knowledge for the tasks
Post-condition	Client received authorization for database access of software
Main scenario	1. Administrator receives the request for the giving permission for database access of software 2. Administrator checks the request validity 3. Administrator fills the application form for the giving permission for database access of software 4. Administrator selects client category based on the quantity of the waste cooking oil 5. Administrator approves the request 6. Administrator prints the instruction for the application use 7. Administrator distributes the instruction to the client as the proof for the successful addition to the users of the waste cooking oil management software for the database access
Alternative	1. In the case if the request is incorrect filled based on the step 2 of the main scenario the administrator returns the request to the client with the instruction how to correct the errors in the request

Each of the users should have individual username and password in order to access to the software. Administrator of information system who needs to maintain the software and he is responsible for working of computer system and software as well. He gives permission to the staff's access to the waste cooking oil management database, maintains database, maintains web presentation of the waste cooking oil management and makes regular daily reports.

Table 2 Specification of use case: Software maintaining

Title	Software maintaining
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the software maintaining
Pre-condition	PC is properly settled Administrator has needed knowledge for the tasks
Post-condition	Backup of the waste cooking oil management software was made
Main scenario	1. Administrator checks if there is some large operation on the software 2. If there is some operation on the software, the administrator waits until the operation ends 3. If there is not operation on the software, the administrator prepares tools for the software maintaining 4. Administrator checks if the all functions of the software are proper 5. If some of the function of the software is not proper than the administrator starts the tool for correction of the function 6. Administrator starts the backup process of the software 7. Administrator records the time of the software backup
Alternative	None

Table 3 Specification of use case: Software web pages maintaining

Title	Software web pages maintaining
Actors	Administrator
Trigger	It starts with the choosing of the option on user interface for the web pages maintaining of software
Pre-condition	PC is properly settled Administrator has needed knowledge for the tasks
Post-condition	Backup of the web pages of software was made
Main scenario	1. Administrator checks if there is some large operation on the web pages of software 2. If there is some operation on the web pages of software, the administrator waits until the operation ends 3. If there is not operation on the web pages of software, the administrator prepares tools for the web pages of waste cooking oil management software maintaining 4. Administrator checks if the all functions of the web pages of software are proper 5. If some of the function of the web pages of education software is not proper than the administrator starts the tool for correction of the function 6. Administrator starts the backup process of the web pages of software 7. Administrator records the time of the web pages of software backup
Alternative	None

Use cases of the software subsystems

Software administration

Administrator performs software administration in order to eliminate all unpredictable errors in the software and system. Administrator has full responsibility for the software maintenance. They will give permissions for other users access to the system, maintains the software, maintains the web pages of the software, maintains the software database, and makes regular daily reports.

Fig. 6 shows the use case diagram of the software administration. As can be seen there are five functions of the administration which will be explained in details by scenarios.

Table 1 shows detailed specification of use case for giving permission for database access of the software by administrator.

Table 2 shows detailed specification of the use case of software maintaining by administrator.

Table 3 shows detailed specification of use case for web pages maintaining of software by administrator.

Table 5 shows detailed specification of use case for making of regular reports by administrator.

Recording of quantity of solid waste

Use case recording of quantity of solid waste is depicted in Fig. 7. The use case diagram has several sub use cases. Table 6 shows detailed specification for use case recording of quantity of solid waste. Fig. 8 shows activity diagram for the recording of quantity of solid waste.

Recording of composition of solid waste

Use case recording of composition of solid waste is depicted in Fig. 7. The use case diagram has several sub use cases. Table 6 shows detailed specification for use case recording of composition of solid waste. Fig. 8 shows activity diagram for the recording of composition of solid waste (Table 7; Figs. 9 and 10).

Fig. 11 Use case diagram – Determining of type of solid waste treatment.

Fig. 12 Use case diagram – Determining of optimal route of solid waste transport.

Determining of type of solid waste treatment

Use case determining of type of solid waste treatment is depicted in Fig. 11. The use case diagram has several sub use cases. As can be seen the module should calculate the cost benefit and emission from collection and transport of solid waste. The module should suggest the type of the solid waste treatment. Also the module should determine the solid waste indicators.

Determining of optimal route of solid waste transport

Use case determining of optimal route of solid waste transport is depicted in Fig. 12. The use case diagram has several sub use cases. The module should calculate the optimal route of the solid waste transport.

Conclusion

Solid waste management present a big issue for all countries. One of the most common solid waste treatment method is disposal. Illegal solid waste disposal and unofficial solid waste recycling could produce high pollution of water, air and soil. There is need for systematic sustainable solid waste management system in order to preserve natural resources and to keep clean the life environment.

The main innovation of the investigation is analyzing and modeling of new software for solid waste treatment. The main suppliers could enter quantity and composition of solid waste in the software. Based on the quantity and composition the clients could decide which treatment and transport route is the best for the solid waste they collected.

Multi-Stage Stamping of Lightweight Steel Wheel Disks by Controlling its Wall Thickness Distribution

Chin Joo Tan, University of Malaya, Kuala Lumpur, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Lightweight metal parts are strongly demanded by industries due to constraints of economy and environment. Particularly, the reduction in weight of automobile parts has great influence on the fuel consumption of vehicles. The low emission of gas CO₂ from the lightweight vehicles prevents global warming. According to carmakers, there is an increase in mileage of 1 km/L of the fuel consumption for 100 kg of the reduction in weight of an automobile. The reduction in weight of the parts also saves cost of the material. The weight of automobile wheels directly driven by an engine has a great influence on fuel consumption of automobiles. Reduction in weight of wheel lowers the un-sprung weight of a vehicle, leading to improved car's handling, particularly in steering precision. A lighter wheel also makes it easier for the car to accelerate and to stop. Fuel consumption is improved with the lighter wheels.

Although aluminum alloy wheels are attractive for the reduction in the weight, the aluminum wheels produced by casting are costly (Fauth, 1980). Moreover, the shock resistant of cast aluminum wheels is lower than steel wheels (Marron, 2002). The mostly produced steel wheels are two-piece structure composed of the disks and rims welded together, and the disks and rims are formed by multi-stage press forming and roll forming operations, respectively as shown in Fig. 1. Marron and Verrier, (1999) have proposed a new concept of structure of steel wheels to decrease the total weight. For the reduction in weight of wheel disks, the thickness distribution is optimized because of a distribution of required strength, i.e., the wall thickness in the portion of high strength is thick and that of low strength is thin. A significant amount of the reduction in weight of the large stamped parts can be obtained by optimizing its wall thickness distribution for the required strength. Although the strength of the disk is determined by the wall thickness at the inner corner of the disk, the wall thickness at the inner corner tends to decrease in the multi-stage press forming including deep drawing. Abe et al. (2002) have prevented the decrease in wall thickness at the inner corner by optimizing drawing ratio and the punch corner in a two-stage forming process of disks. Mori et al. (2003) have developed a combined forming process of deep drawing and ironing for attaining optimum distributions of wall thickness in the wheel disks. It is desirable in automobile industry to develop forming processes for increasing the wall thickness at the inner corner. For the reduction, the application of high strength steel sheets to steel wheels tends to increase in wheel making industry (Hibon et al., 1996).

The most common type of wheel for passenger cars is made of mild steel due to low cost. According to the rotating bending fatigue test of the steel wheels (Tanaka et al., 1987), cracks tend to occur at the inner corner and the hat portion of the wheel disk as shown in Fig. 2. Since the wall thickness at the inner corner tends to decrease in the conventional multi-stage stamping of the wheel disk, large thickness blanks have been employed in the multi-stage stamping process to satisfy the high requisite strength at the inner corner, and the increase in weight results. Although the wheel disk formed from the circular tailor welded blank has optimum material strength and thickness distribution (Marron and Verrier, 1999), the welding of three or more pieces of sheet for obtaining the local thickening is not practical and costly (see Fig. 3). The control of the wall thickness distribution of the wheel disk by stamping processes is preferred due to high productivity and low cost.

Fig. 1 Forming process of steel wheel.

Fig. 2 Locations of cracks in rotating bending fatigue test of steel wheel.

Fig. 3 Tailor blank having local thickening formed from different parts by laser welding.

Fig. 4 Conventional multi-stage forming process of wheel disk.

Multi-Stage Stamping of Lightweight Steel Wheel Disk

Conventional Process

The disks in the steel wheels are formed by multi-stage sheet metal forming operation shown in Fig. 4. The blank is deeply drawn in the 1st stage, and then the cup with a flange is redrawn in the 2nd stage. In the 3rd, 4th and 5th stages, the flange of the disk is formed, and the wall thickness at the inner corner of the disk hardly changes in these stages. Since the inner flat region of the disk is connected to the driven shaft, the requisite strength at the inner corner is high, and thus the wall thickness of the corner is set to be large in the design of products. The wall thickness at the inner corner, however, becomes small due to the stretching during the deep drawing and redrawing in the 1st and 2nd stages. To satisfy the requisite strength at the inner corner, the thickness of the blank becomes large, and thus the increase in weight of the wheel disk results.

Increase in Wall Thickness at Inner Corner of Drawn Cup With Flange Using Conical Punches

The increase in wall thickness at the inner corner of the drawn cup with a flange by compression is illustrated in Fig. 5 (Tan et al., 2007). Since the portions in the 1st and 2nd stages equivalent to the inner corner after the 3rd stage are not located near the punch corners, the local thinning in the 1st and 2nd stages is prevented. In the 3rd stage, the side wall and conical bottom of the cup are compressed with the outer punch. Finally, the bottom of the cup is formed with the inner punch into the flat one in the 3rd stage. The wall thickness at the inner corner hardly changes in the 4th and 5th stages. Only the first three-stage forming process is dealt with in the present study.

Fig. 5 Increase in wall thickness at inner corner of drawn cup by compression. Reproduced from Tan, C.J., Abe, Y., Mori, K., Nonaka, T., Ebihara, O., 2007. Increase of wall thickness around corner of multi-stage drawn cup with flange using conical punches. *Key Engineering Materials*, 340–341, pp. 761–766.

Fig. 6 Conditions for 3-stage forming of drawn cup with flange. Reproduced from Tan, C.J., Abe, Y., Mori, K., Nonaka, T., Ebihara, O., 2007. Increase of wall thickness around corner of multi-stage drawn cup with flange using conical punches. *Key Engineering Materials*, 340–341, pp. 761–766.

The detailed experimental conditions for the 3-stage forming process of the drawn cup with a flange are shown in Fig. 6. The same conical punch angle θ was employed in the 1st and 2nd stages to avoid local thinning around the portion equivalent to the inner corner. The punch angle and stroke in the 1st and 2nd stages were changed in the experiment to increase the wall thickness around the inner corner after the 3rd stage. The experiment of the 3-stage forming process of mild steel blanks having an initial thickness of 1.6 mm was performed. The size of the disk is approximately 1/3.5 of the actual one. All contact surfaces were lubricated with a press oil except the interfaces involving the conical punches were kept dry.

Definition of Drawn Volume

The increase in wall thickness at the inner corner is greatly influenced by the drawn volume into the die after the 2nd stage shown in Fig. 7, because the drawn volume is compressed in the 3rd stage. The drawn volume V after the 2nd stage is approximated by

$$V = \frac{\pi \{D_0^2 - [D_2^2 - (D_{D2} + 2R_{D2})^2]\}t}{4} \quad (1)$$

Where,

D_0 is the initial diameter of the blank, D_2 is the outer diameter of the cup after the 2nd stage, D_{D2} is the diameter of the die in the 2nd stage, R_{D2} is the corner radius of the die in 2nd stage and t_0 is the initial thickness of the blank.

The relationships between the punch angle and the punch stroke in the 2nd stage for maintaining same $V \approx 7700 \text{ mm}^3$ are given in Fig. 8. As the punch angle in the 2nd stage increases, the punch stroke is increased to maintain is at the same drawn volume level. The punch stroke in the 1st stage is approximately 10% less than the 2nd stage.

The wall thickness distributions of the drawn cups with a flange after the 3rd stage for $\theta = 0^\circ$, 15° , 25° and 30° obtained from experiment are shown in Fig. 9. A maximum 12.5% increase in thickness at the inner corner for $\theta = 25^\circ$ was obtained. For the large punch angle, the thinning at the center of the cup occurs. Since the central portion of the cup is punched as a hub hole of the wheel, this thinning is not a defect. In the fatigue test of the steel wheel disk, the crack also occurred at the hat portion (Marron and Verrier, 1999). The fatigue strength of the steel wheel is greatly improved from the increase in wall thickness at the hat portion.

Fig. 7 Definition for drawn volume.

Fig. 8 Relationships between punch angle and punch stroke in 2nd stage for maintaining same $V \approx 7700 \text{ mm}^3$. Reproduced from Tan, C.J., Abe, Y., Mori, K., Nonaka, T., Ebihara, O., 2007. Increase of wall thickness around corner of multi-stage drawn cup with flange using conical punches. Key Engineering Materials, 340–341, pp. 761–766.

Fig. 9 Wall thickness distributions of drawn cups with flange after 3rd stage for $\theta = 0^\circ, 15^\circ, 25^\circ$ and 30° obtained from experiment.

Fig. 10 Buckling at hat portion of drawn cup after 3rd stage for $V \approx 8840 \text{ mm}^3$. Reproduced from Tan, C.J., Abe, Y., Mori, K., Nonaka, T., Ebihara, O., 2007. Increase of wall thickness around corner of multi-stage drawn cup with flange using conical punches. Key Engineering Materials, 340–341, pp. 761–766.

Although it is possible to further increase the wall thickness around the inner corner in the 3rd stage with large drawn volume, buckling was observed in the cup after the 3rd stage for $V \approx 8840 \text{ mm}^3$ due to the excessive compression as shown in Fig. 10. The increase in the drawn volume after the 2nd stage is limited by the occurrence of buckling.

Conclusion

The reduction in weight of automobile parts is strongly demanded to improve fuel consumption of automobiles. Since forming processes are utilized for production of a lot of automobile parts because of high productivity, optimization of forming processes is a key to the reduction in weight. It is increasingly important to control the wall thickness distributions of products by forming. In this paper, the wall thickness at the inner corner of a wheel disk obtained from experiment was successfully increased by 12.5% for the punch angle of 25° in the 1st and 2nd stages. The reduction in weight of the wheel disk can be obtained by decreasing the blank thickness.

Introduction

Nanomaterials (NMs) have attracted intense research interests due to their application potential in various fields of science and technology such as health care, food, textile and electronics (OECD Environment Directorate, 2014). As the characteristics of NMs fall between single atom and bulk materials, they generally exhibit unique and significantly improved but sometimes unpredictable physical, chemical, and biological properties which are different from their bulk materials (nanoDE-Report, 2013). The NMs contain at least one structural dimension at the nanoscale (10^{-9} m) and they are classified according to the dimensions of their structural elements like zero (0D), one (1D), two (2D), and three (3D) dimensional. All the 0D, 1D, 2D and 3D nanostructures can be amorphous or monocrystalline. Nanomaterials can also be brittle or ductile. There are various types of NMs and depending on their construction, they are currently classified as (i) carbon-based, (ii) metal-based, (iii) dendrimers, and (iv) composites (Saleh, 2016).

Carbon-based NMs are receiving special attention in the scientific and engineering community because of their multi-faceted superiority in thermal conductivity, flame retardancy, mechanical stability and biocompatibility (Liu *et al.*, 2018). Metal based nanomaterials have drawn significant attention as energy storage devices. These electrochemical energy storage (EES) devices with their high efficiency, versatility and adaptability have emerged as one of the most promising energy storage systems. Batteries and supercapacitors are the two types of EES devices, whose performance is largely dependent on electrode materials (Khaligh and Li, 2010; Beidaghi and Wang, 2012).

Ideally the electrode materials should possess porous structures with high surface area, high electrical conductivity and excellent recycling capability (Yu *et al.*, 2015). Micro-sized EES devices have customized configuration as well as excellent mechanical stability for easy insertion into other micro-electronics (Gogotsi and Simon, 2011; Wang *et al.*, 2014). Moreover, easy ion transport is another requirement with the real capacitance and energy density. However, the bulk form of material with high capacity and energy density exhibits surfaces that are unstable or reactive in electrochemical environment when downsized to nanometer length scales. Hence, the manufacturing strategy and surface engineering play important roles to overcome the bottlenecks of EES from NMs.

Dendrimers are man-sized symmetric molecules. The surface of a dendrimer has many chain ends and as a result there can be change in size, shape, and adaptability to another element (Mendes *et al.*, 2017). Furthermore, three-dimensional dendrimers can have inside cavities into which different particles can be set for different applications in both biological and materials sciences (Mendes *et al.*, 2017). The properties of composite NMs can be designed according to their application or requirement and the properties are dependent on the choice of matrix, curing phase, shape and orientation (Sahay *et al.*, 2014).

However, in this review, we outline the synthesis and production of low cost carbon NMs and their applications, different energy storage devices from NMs and the advances in manufacturing and surface engineering to produce reliable and efficient EES. Such efforts may be helpful for proper expansion of applications and research interest toward further development of nanotechnology.

Carbon Nanomaterials (CNMs)

Carbon is a unique element in the periodic table which acts as the basis of all forms of life on earth. Carbon-based nanomaterials with their exceptional characteristics are promising candidates for future areas of important applications. The dimensionalities in carbon nanomaterials range from zero, one, two and three dimensional structures such as fullerenes, carbon nanotubes (CNTs), nanofibers, graphene and nanodiamond (Ravi and Vadukumpully, 2016). The CNTs were first reported in 1991 (Iijima, 1991) and graphene was discovered in 2004 (Novoselov *et al.*, 2004). Both of them exhibit extraordinary mechanical strength and electrical conductivity, remarkable physical and chemical properties which make them attractive for use as key components in catalysts, biosensors, fuel cells, batteries and electronic devices (Deng *et al.*, 2016; Xu *et al.*, 2014; Avouris and Dimitrakopoulos, 2012; Kumar *et al.*, 2016). Graphene is a flat monolayer of carbon atoms tightly packed into a 2D honeycomb lattice, and it can be considered as the mother form of all the other carbon nanostructures. This can be wrapped up into 0D fullerenes, rolled into 1D tube or stacked into 3D graphite (Fig. 1).

Carbon dots (CDs) and graphene quantum dots (GQDs) are receiving tremendous attention for a wide range of applications due to their attractive properties like chemical inertness, tunable photoluminescence, nontoxicity and excellent biocompatibility (Wang *et al.*, 2016; Zhu *et al.*, 2015; Zhang *et al.*, 2017a; Kozák *et al.*, 2016; Yew *et al.*, 2017). Though there is numerous fabrication

Fig. 1 Graphene as a 2D building material for carbon materials of all other dimensionalities: 0D fullerenes, 1D nanotubes or 3D graphite. Adapted from Ravi, S., Vadukumpully, S., 2016. Sustainable carbon nanomaterials: Recent advances and its applications in energy and environmental remediation. *J. Environ. Chem. Eng.* 4, 835–856.

strategies, the mass production of environment friendly carbon based nanomaterials at low cost is still a major challenge. The high cost of production has restricted the commercialization of these materials. Hence, green fabrication routes to prepare carbon based nanomaterials via cost-effective approaches are of great interest.

Coal and biomass or waste residues have gained momentum in carbon nanomaterial research (Hu *et al.*, 2016). Coal is a heterogeneous material with a three dimensional cross-linked network. It consists of aromatic and hydro aromatic units which are connected by short aliphatic and ether linkages (Ye *et al.*, 2013; Vasireddy *et al.*, 2011).

The carbon concentration varies from 70 wt% in lignite to 75 and 85 wt% in sub-bituminous and bituminous coal respectively, and reaching 94 wt% in anthracites (Vasireddy *et al.*, 2011; Mathews and Chaffee, 2012). In addition, coal is a low-cost resource abundantly available in nature (Hu *et al.*, 2016; Vasireddy *et al.*, 2011; Islam *et al.*, 2017; Dong *et al.*, 2014; Tilman *et al.*, 2006) and, thereby, making coal a promising carbon source for the preparation of nanomaterials.

One of the rich sources of carbon is renewable sources like biomass and waste residues. They are available in plenty and are cost-effective and renewable. Several promising reports have emerged in the recent years on the synthesis of carbon nanomaterials from inexpensive resources through commercially viable and environmental friendly approaches (Hu *et al.*, 2016).

Synthesis and Properties of Carbon Nanomaterials From Coal and Sustainable Resources

Diverse classes of coal and sustainable resources to synthesize carbon based nanomaterials are shown in Figs. 2 and 3 (Ravi and Vadukumpully, 2016; Hoang *et al.*, 2018) along with a discussion on the relevant properties.

Carbon nanotubes (CNTs) from coal

There are various techniques for the production of CNTs of which thermal plasma, chemical vapor deposition (CVD) and arc discharge are noteworthy. Tian *et al.* (2004a) first developed the thermal plasma method for the production of multi-walled CNTs (MWCNTs) by injecting Baode coal fine powders of 5–25 μm size directly into an arc plasma jet. The obtained MWCNTs had interlayer 0.343 nm spacing and length 7 μm . The Raman spectra showed 2 peaks at 1600 and 1291 cm^{-1} , corresponding to G (graphitic order) and D (defect signal) peaks, respectively. The low value of I_G/I_D ratio, illustrates the low-graphitized MWCNTs. However, the addition of 5 wt% Cu powder to coal promoted the yield of CNTs. The effect of three catalysts (Cu, Fe and Co) on the formation of CNTs was found to be significant (Tian *et al.*, 2004b).

Using Cu as catalyst, the diameter of MWCNTs was in the range of 50–70 nm and the yield of CNTs with Cu catalyst (5%) was higher than compared to Fe or Co (1%). Chemical vapor deposition (CVD) is another technique which is widely employed at large-scales to produce CNTs (Moothi *et al.*, 2012). In 2015, Moothi *et al.* (2015) produced CNT from the Bank Colliery-Witbank coal, South Africa at a pyrolysis temperature of 400–750°C and the resultant gases composed of CH_4 and CO were then fed to a vertical reactor tube at 900°C for CNT synthesis with ferrocene as a catalyst. In Fig. 4 the TEM images of CNT at different pyrolysis temperatures are given.

With the increase of pyrolysis temperature, the dimensions of CNT reduce significantly. Song *et al.* (2018) demonstrated the fabrication of MWCNTs from coal tar pitch in an alumina tube furnace with $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ as a catalyst. Cobalt accelerated C_2H_4 dissociation via electron donation effect, followed by the formation of straight MWCNTs through diffusion-precipitation mechanism. Ultimately, at the pyrolysis temperature of 1173 K with 0.75 wt% Co clusters, the optimized quality of CNTs ($I_G/I_D = 1.19$) was achieved with diameter of 40 nm and length of 200 μm .

Fig. 2 Various types of coal as precursors for synthesizing carbon based nanomaterials. Reproduced from Hoang, V.C., Hassan, M., Gomes, V.G., 2018. Review coal derived carbon nanomaterials – Recent advances in synthesis and applications. *App. Mater. Today* 12, 342–358.

RAW MATERIALS

WASTE MATERIALS USED AS FEEDSTOCKS FOR CNM GENERATION

Fig. 3 Feedstocks pyrolyzed (from left to right): Corn residue, sugar cane bagasse, waste tyres, postconsumer PE and PET. Reproduced from Ravi, S., Vadukumpully, S., 2016. Sustainable carbon nanomaterials: Recent advances and its applications in energy and environmental remediation. *J. Environ. Chem. Eng.* 4, 835–856.

Carbon nanotubes (CNTs) from sustainable sources

High quality CNTs and related structures can be manufactured from relatively inexpensive feedstock like waste plastics post-consumer PE and PET, agricultural wastes (sugar cane bagasse and waste corn residue obtained after extracting the starch fraction of corn for bioethanol production, scrap tyre chips, etc. (Zhuo *et al.*, 2012)).

The granulated solid feedstocks were first pyrolyzed in a furnace in an inert atmosphere (nitrogen) to generate gaseous carbon containing components. The gases were directed to a venturi where they were mixed with pre-heated oxygen containing gases or with additional inert gases. The fuel to oxygen ratio was pre-adjusted to fuel-rich condition to ensure adequate amount of carbon containing components, hydrogen and water vapor are formed for the growth of CNTs. The partially oxidized effluent was then synthesized in a second furnace synthesis reactor with fixed catalyst substrate for the growth of CNTs. The operating temperatures of both the pyrolysis furnace and the synthesis reactor were in the range 600–1000°C. The shapes and sizes of CNTs from the waste are presented in **Table 1** (Ravi and Vadukumpully, 2016) and TEM images are given in **Fig. 5** (Zhuo *et al.*, 2012).

Fig. 4 TEM images of CNTs produced at a temperature of 900°C in the CVD reactor with coal pyrolysis reactor temperatures of (a) 400, (b) 450, (c) 500, and (d) 550°C. Reproduced from Moothi, K., Simate, G.S., Falcon, R., Iyuke, S.E., Meyyappan, M., 2015. Carbon nanotube synthesis using coal pyrolysis. *Langmuir* 31, 9464–9472.

Table 1 CNTs synthesized from waste

Residue source	Shape	Size
Corn	Twisted structure with irregular shape	100–200 nm (width)
Sugar bagasse	Straight, smooth cylindrical shape	~50 μm long, dia 20.8 nm
Waste tyre	Long, entangled braid-like	~40 μm long
PE	Hollow	1–5 μm long, dia 15.8 nm

Raman spectroscopy showed strong peaks of the G-band, indicating the presence of graphitic carbon (Dresselhaus *et al.*, 2010). Besides, there were peaks of 2D and D bands, signifying the presence of parallel graphite layers and disordered structure or impurities respectively. The I_G/I_D ratio was higher for the bagasse and least for tyre waste. The effluents of biomass waste were rich in methane and other light aliphatic compounds. The effluents for PET had high mole fraction of benzene, whereas, PE effluents were rich in ethylene, propylene and acetylene. Hence, biomass waste is a promising source to provide carbon feedstocks for generating various carbon nanostructures and also cogenerate syngas.

Graphene and related structure from coal

There are various techniques to fabricate graphene. Awasthi *et al.* (2015) formed graphene like nanosheets using annealed bituminous coal as an anode under H_2 gas environment using the arc discharge set-up. Graphene in the product was confirmed by the hexagonal pattern in TEM images, together with the evidence of D (1346 cm^{-1}), G (1573 cm^{-1}) and 2D (2688 cm^{-1}) in Raman spectra. In 2014 Graphene nanosheets were also fabricated by Xu *et al.* (2014) through pyrolysis of coal tar pitch at 1700°C using Al powder as a catalyst. The Raman spectrum exhibited a weak D band at 1351 cm^{-1} and strong G band at 1583 cm^{-1} with I_D/I_G of 0.26. A symmetric 2D peak at 2695 cm^{-1} with an intensity ratio of 2D to G (I_{2D}/I_G) bands of 0.82 was also obtained, illustrating that the product comprised few-layer graphene sheets with small amount of defects.

Graphene and related structure from sustainable sources

Wastes with low or negative monetary value like common solid waste, grass blades, dog feces and cockroach legs are used as carbon source. In a tube furnace under H_2/Ar environment, the solid carbon sources are decomposed or diffused to the backside of Cu foil at 1050°C . High quality pristine graphene with few defects and ~97% transparency is confirmed by Raman and UV-vis spectroscopy. In XPS analysis, no heteroatoms were detected (Ruan *et al.*, 2011). High quality graphene was also extracted from hibiscus flowers and lotus petals (Ray *et al.*, 2012) by thermal exfoliation using Ar gas at a temperature of 1600°C . Graphene was also produced from sugar cane. Sugar coated sand was heated in silica crucible in a furnace at 750°C for 3 h in N_2 atmosphere. The composite has application in water purification.

Fig. 5 TEM images taken at low magnification (A) and high magnification (B) of carbon nanomaterials derived at optimum conditions from carbon feedstock such as (1) waste corn residue (2) waste sugar cane bagasse (3) waste tyres, and (4) PE. Reproduced from Zhuo, C., Joner, O. A., Tenorio, J.A.S., Levendis, Y.A., 2012. Synthesis of carbon nanomaterials through up-cycling agricultural and municipal solid wastes. *Ind. Eng. Chem. Res.* 51, 2922–2930.

Many natural products like proteins, vitamin C, glucose, green tea solution (Liu *et al.*, 2010a; Zhang *et al.*, 2010; Zhu *et al.*, 2010; Wang *et al.*, 2011b) are used as reducing agents to produce graphene from GO. The polyphenol (TPs) in green tea is biocompatible and biodegradable and schematic illustration of TP reduced graphene is shown in Fig. 6. The synthesized graphene opens up interesting bio applications.

Graphene quantum dots (GQDs) from coal

GQDs are a new class of materials that have attracted worldwide research attention in the past few years due to exceptional spin (Trauzettel *et al.*, 2007), electronic (Ritter and Lyding, 2009), and optical properties (Ritter and Lyding, 2009). Chemical oxidation is the most widely implemented technique to fabricate GQDs from coal.

The size of GQDs can be easily tuned by the use of different coal precursors and the fluorescence can be varied by the change of temperatures. It was first reported by Ye *et al.* (2013) that GQDs can be fabricated from 3 different types of coals which are bituminous, coke and anthracite in a facile one-step. Bituminous coal is chemically oxidized in a mixture of concentrated H_2SO_4 and HNO_3 acids at 100 and 120°C for a day, followed by neutralization to pH 7 and dialysis for 5 days to obtain b-GQDs. The size and thickness of GQDs were 2.96 ± 0.96 and 2.30 ± 0.78 nm and 1.5–3 nm (Fig. 7(a–d)) respectively. Raman spectra revealed the value of I_D/I_G to 1.55 ± 0.19 . Green and strong blue fluorescence were emitted at 500 and 460 nm respectively at 345 nm UV irradiation.

The size of GQDs was adjusted to 29 ± 11 and 5.8 ± 1.7 nm by choosing anthracite and coke as starting materials and the intensity of D to G peaks I_D/I_G obtained were 1.90 ± 0.22 and 1.28 ± 0.18 respectively. The emitted fluorescence was of yellow and green with maximum emission wavelength at 530 and 480 nm, respectively. By changing the oxidation temperature, the same group produced GQDs of different size ranges and luminescence (Ye *et al.*, 2015).

It was also found that GQDs/PVA composite film emitted white photoluminescence (PL) under UV light and the peak intensity was obtained at 10% loading of GQDs. The quantum yield was obtained at 0.5% (He *et al.*, 2014). The properties of electrospun carbon nanofiber fabrics improved significantly when bituminous derived GQDs was used to a polyacrylonitrile (PAN) solution, followed electrospinning and carbonization at 1000°C under N_2 gas (Zhu *et al.*, 2018).

Graphene quantum dots (GQDs) from sustainable sources

There are various natural sources to produce GQDs but microwave assisted hydrothermal process using glucose as precursor showed promising result (Tang *et al.*, 2012). The authors also suggested that most of the carbohydrates which contain C, H and O in the ratio of 1:2:1 (sucrose, fructose) could also be used as the carbon source to prepare GQDs provided that H and O exist in the form of hydroxyl, carboxyl or carbonyl groups. The size of the GQDs could be tuned from 1.65 to 21 nm by simply extending the heating time from 1 to 9 min, respectively (Fig. 8).

The GQDs display deep ultraviolet emission at 4.1 eV. However, the emission wavelength is independent of the size of the GQDs. Fig. 9 shows the PL properties of the microwave assisted synthesized GQDs.

The emission peak is varied with the excitation frequency. The various functional groups present on the GQD surface acted as “surface state” energy levels between π and π^* states of $\text{C}=\text{C}$. These functional groups possess various energy levels resulting in a series of emissive traps. When a particular excitation wavelength irradiates the GQDs, the surface state emissive trap would dominate the

The left-most vial is the GQDs solution with size of 4.5 ± 1.2 nm, then 16 ± 1.33 , 41 ± 6.4 nm and the right-most vial is the GQDs solution with size of 70 ± 15 nm. Reproduced from Ye, R., Peng, Z., Metzger, A., *et al.*, 2015. Bandgap engineering of coal-derived graphene quantum dots. *ACS Appl. Mater. Interfaces* 7, 7041–7048.

emission. With change in excitation wavelength, the surface state emissive trap that dominates the emission would also change. The GQDs are capable of converting blue light into white light when the GQDs are coated onto a blue light emitting diode. Due to the luminescence stability, biocompatibility, low toxicity and high water solubility, these GQDs function as outstanding probes for high contrast bio imaging and sensing applications. Since the PL is tunable, these GQDs find interesting applications in optoelectronics. **Fig. 10** shows the UV-vis absorption spectra and the PL spectra of the GQDs derived from carbon fibers.

It is evident that the reaction temperatures affect the absorption properties of the as synthesized GQDs since there is a clear blue shift from 330 to 270 nm with increasing temperature. The temperature could also change the distribution of emission wavelength of the GQDs.

Carbon dots (CDs) from coal

Carbon nanoparticles less than 10 nm in size are amorphous in nature and are called carbon dots. They have excellent optical properties and fluorescence emissions and are ideal candidates for numerous applications in sensing, bio-imaging and photo voltaic (Wang *et al.*, 2011a). Similar to GQDs, CDs are also produced by a top-down strategy as listed in **Table 2** (Hoang *et al.*, 2018).

Chemical oxidation is simple and effective in large-scale production of CDs from coal. However, the use of strong oxidizing agent (e.g., HNO_3), releases toxic gases, and the removal of excess acid is quite costly. Therefore, green and safe strategies were developed where, Hu *et al.* (2016) employed H_2O_2 to oxidize anthracite at 80°C for only 3 h to produce CDs. The excess hydrogen peroxide could

Fig. 9 PL properties of the GQDs. (a) The PL spectra of the GQDs excited by various wavelengths; (b) the absorbance and excitation spectra of the GQDs solution; (c) the normalized PL spectra of the GQDs with various sizes; (d) the GQDs solutions irradiated by ambient light (top) and 365 nm UV lamp (bottom). The GQDs were prepared with 11.1 wt% glucose solution for 5 min (a and b), 5–9 min (c), 1–11 min (d) microwave heating at 595 W. Reproduced from Gupta, V., Chaudhary, N., Srivastava, R., *et al.*, 2011. Luminescent graphene quantum dots for organic photovoltaic devices. *J. Am. Chem. Soc.* 133, 9960–9963.

be removed by simple solution boiling. The fabricated CDs were in size range of 1–3 nm and crystalline structure with (100) lattice spacing of 0.21 nm exhibited a wavelength dependent PL property and emitted cyan fluorescence when excited at 365 nm.

When the CDs were further functionalized with ethylene diamine (EDA), a red shift in the PL emission with emission maxima at ~510 nm and green fluorescence at 375 nm UV irradiation was obtained. [Thiyagarajan *et al.* \(2016\)](#) synthesized CDs of tunable size and surface functionalization by refluxing, microwave irradiation and laser ablation from lignite using an EDA solution. The obtained CDs which were 35–90, 20–50 and 2.5–5.5 nm in size and all had excitation dependent PL behavior with maximum emission wavelength at ~468, 435 and 403 nm, respectively. The CDs were also obtained by refluxing and microwave irradiation methods which exhibited an absorption peak at ~260 nm due to $\pi - \pi^*$ transition of C = C bonds and shoulder at ~325 nm assigned to $\pi - \pi^*$ transition of the surface functional groups whereas the former peak shifted to ~220 nm in the case of CDs prepared by laser ablation strategy. However, low PL quantum yields were achieved ($\leq 6\%$ for all samples).

Carbon dots (CDs) from sustainable sources

Orange juice is a natural bio resource with key components sucrose, fructose, glucose, citric acid and ascorbic acid. Highly fluorescence CDs are obtained by hydrothermal treatment as shown in [Fig. 11](#). It is nontoxic with good stability and of PL

Table 2 CDs synthesized from different types of coal

Precursor	Product	Fabrication route	Diameter, nm	Yield, %	Quantum yield, %	Optical properties	
						$\lambda_{em, max}, nm$	Color under UV light
Coal	CDs	Chemical oxidation	3–5				
Lignite	CDs	Refluxing	35–90	4.5		468	
		Microwave irradiation	20–50, average 35	5.1		435	
		Laser ablation	2.5–5.5, average 3.5	6		403	
		Laser ablation and dispersion in Na ₂ SO ₄		34.5		493	
Coal tar	CDs	Chemical oxidation and solvothermal	1.5–4.5	29.7		605	Orange (toluene)
	Liposome/CDs composite		50–100	10.7		640	Blue (toluene), white (H ₂ O)
Anthracite	N-doped CDs	Solvothermal	4.7	25.6	47	445	Cyan
Anthracite	CDs	Chemical oxidation	1.96 ± 0.73	7	Relative QY ~0.67	420	
		Calcination at 900°C and Chemical oxidation	2.27 ± 0.74	30	Relative QY ~0.7	420	
		Calcination at 1500°C and Chemical oxidation	3.1 ± 0.8	5	Relative QY ~1	505	
	Reduced CDs	NaBH ₄ reduction of CDs-900			8.8	400	Blue
Anthracite	CDs	Chemical oxidation	1–3	50–60		455	Cyan

quantum yield of 26%. The process is green and cost effective as there is no use of strong acid or passivation agents during synthesis (Bourlinos *et al.*, 2012; Zhang *et al.*, 2012). However, to improve the electronic properties, enhanced surface and local chemical reactivity, Hu *et al.* (2016) doped CDs with ultra-small nitrogen (N) and sulfur (S) (N, S-CDs) which was synthesized from rice and N-acetyl-L-cysteine (NAC) by microwave assisted pyrolysis.

The N, S-CDs had enhanced PL properties compared to undoped CDs. The size was found to be 1.4 nm. The effect of mass ratios of NAC to rice (NAC/rice) on the N, S-CDs were explored using HPLC-FD. The higher NAC/rice ratio aided the synthesis of N, S-CDs with enhanced fluorescence emission as depicted in Fig. 12.

Heteroatoms doped CDs are also synthesized using natural hair (Dong *et al.*, 2013) and goose feathers (Liu *et al.*, 2015b). The obtained S-N-CDs from natural hair retained good biocompatibility, low toxicity and excellent solubility in polar solvents. The CDs obtained from goose feathers had high PL efficiency of 17.1% and demonstrated highly sensitive and selective detection behavior of Fe³⁺ ions with detection limit as low as 196 nm.

Porous Carbon Nanomaterials

Porous carbon nanomaterials have attracted great research interest in the recent past due to high surface area with open and accessible porosity (Li *et al.*, 2003). As a result, they are the potential candidates for application in separation, electro catalysis and energy storage (Li *et al.*, 2003; Liang *et al.*, 2003; Hyeon *et al.*, 2003). Carbon and natural resources can be used as a precursor to produce carbon nanomaterials.

Carbon source

Lignite, high volatile bituminous, low volatile bituminous and anthracite are four types of coal used by Keller *et al.* (2016) as carbon source for the preparation of thin film of carbon nanoparticles. The coals were ball-milled with isopropyl alcohol (IPA) for 106 h and centrifuged to obtain coal particles with diameters less than 100 nm. The nanoparticles were spin-coated onto a silicon wafer or a quartz substrate to fabricate thin films. It was found that the most uniform thickness with little cracking of the film was achieved from high volatile bituminous coal. Finally, thermal treatment of the film led to a change in sp^2 allotropes and aromatic unit size, allowing the variation of its electrical conductivity in over seven magnitude orders (conductivity $\sim 10^{-6}$ S m^{-1}). The Raman spectra indicated that I_D/I_G ratio increased steadily as the annealing temperature rose from 450°C to 950°C for high volatile bituminous and anthracite films, indicating a remarkable rise in carbon disorder. In addition, the optical gaps associated with $\pi - \pi^*$ transition were found to be 1.8 and 0.68 eV for high volatile bituminous and anthracite films respectively. Interestingly, the gap was reduced to 0 eV at annealing temperature 800°C, indicating the tunability of optical band gaps of the thin films.

Low grade carbon (Das *et al.*, 2016) and carbon tar (Zhang *et al.*, 2017c) were also explored to synthesize carbon nanoparticles. The graphitization level was low for carbon nanoballs from low grade coal which necessitated further purification of nanoballs. Whereas, nanoparticles from tar are very sensitive to calcination temperature where there is gradual collapse of carbon crystal structure with the increase of temperature. Carbon nanofibers have been fabricated from coal of Xinjiang, China by electrospinning (Zhao *et al.*, 2014). The activated carbon nanofibers were treated with a mixture of HNO_3 and H_2SO_4 (1:3, v-v) and polyacrylonitrile (PAN) solution. The prepared sample was further carbonized and steam activated at 800°C to obtain activated carbon nanofibers. Pt/Co carbon nanofibers from coal (Pt/Co-CF) were synthesized from acid treated coal and cobalt acetate which were mixed with PAN and N, N – dimethylformamide (DMF) before electrospinning and carbonization to foster cobalt embedded carbon nanofiber (Co-coal-CF) (Mu *et al.*, 2017). The average crystal size of Pt nanoparticles in Pt/Co-coal-CF was 3.6 nm and the lower I_D/I_G ratio indicated higher degree of graphitization.

Sustainable source

Wood and cotton are suitable precursors for porous carbon structures as they are made of carbon rich organic polymers like cellulose, hemicellulose and lignin. The precursors are loaded with conducting polymer Polypyrrole and Fe catalyst and highly graphitic nanostructures are obtained after microwave treatment. The catalyst Fe was removed by an acid leaching process and nanostructures of 350.95, 431.29 and 293.19 m^2/g were obtained from wood, cotton and filter paper respectively as presented in Fig. 13.

Microporous carbon structure with high specific area of 2511 m^2/g were obtained from EFB of palm oil trees by Parshetti *et al.* HTC method was adopted following activation with KOH (Parshetti *et al.*, 2015). The produced nanoparticles were found to be useful as adsorbents in CO_2 capture applications. A wide variety of diverse sources have been explored as prospective resources for porous carbons which are: cherry stones and olive (Caballero *et al.*, 2011), mangrove charcoal (Liu *et al.*, 2010b), alginic acid (Wu *et al.*, 2010), rice husk (Wang *et al.*, 2013a), banana fibers (Stephan *et al.*, 2006), peanut shells (Fey *et al.*, 2003), waste coffee grounds (Yun *et al.*, 2015), sugarcane bagasse (Wahid *et al.*, 2014) and natural yoghurt (Wahid *et al.*, 2015). Activated graphene also possess outstanding electrochemical performance similar to porous carbon, because of its open and relatively flat adsorption surfaces (Zhu *et al.*, 2011). Wang *et al.* (2013b) have used hemp bast fiber (Cannabis sativa) as the precursor to produce graphene-like nanosheets by combination of hydrothermal and activation processes. Hemp bast fiber has a multilevel layered structure consisting of cellulose, semi cellulose, and lignin. The resulting structure comprised of interconnected 2D carbon nanosheets (CNS) with high degree of mesoporosity. The obtained CNS has high specific surface area in the range of 1505–2287 m^2/g and with good electrical conductivity. The SEM and TEM images of CNS obtained at 800°C activation temperature are presented in Fig. 14.

Applications of Carbon Nanomaterials

The carbon nanomaterials derived from different sources have multitude of applications ranging from environmental (Gong *et al.*, 2015), catalytic (Gao *et al.*, 2015a), electrical (Wang *et al.*, 2013b) and to biological (Sahu *et al.*, 2012). The following section briefly discusses some of the applications of these carbon nanomaterials in environmental and renewable energy related areas.

Adsorbents in Water Purification and Gas Uptake

The adsorbent plays an important role for the elimination of industrial pollutants from waste water. CNTs (Khin *et al.*, 2012), graphene (Li *et al.*, 2011), ordered mesoporous carbon (Zhuang *et al.*, 2009) and activated carbon (Hameed *et al.*, 2007) are used as adsorbents. PCNS derived from waste plastics exhibited superior characteristics as an adsorbents and adsorption capacity was found to be 769.2 m^2/g which was much higher than that of graphene, activated CNT, porous MnO_2 microsphere etc., as demonstrated in Fig. 15. The material also exhibits outstanding recyclability i.e., even after 10 cycles, adsorption capability of 692 m^2/g retained. MG is cationic dye which is widely used in textile, leather and paper industries as a coloring agent. It is extremely toxic and known to cause carcinogenesis and respiratory toxicity (Ahmad and Alrozi, 2011; Scott *et al.*, 2013). The effluent from the industries contain considerable amount of this dye which is difficult to remove. HTC of pine needles at 225°C and subsequent oxidation using H_2O_2 resulted in hydro char that could effectively remove organic dye MG from waste water.

One of the major environmental challenges is the global warming and a key factor to this is the emission of greenhouse gases like CO and CO₂ (Scott *et al.*, 2013). Carbon capture and storage is a prospective approach towards lessening the emissions from industrial sources (Haszeldine, 2009). Porous carbon materials are attractive class of adsorbents due to their low-cost, large surface area, better availability, hydrophobicity, resistance to acidic and basic conditions. The microporous carbon from EFB has a CO₂ uptake capacity of 3.71 mmol/g at 25°C and at a pressure of 1 atm (Fig. 16) (Parshetti *et al.*, 2015).

Hydrogen is considered as a clean form of energy and is the fuel for tomorrow. There are various modes of its production, but the major challenge is to store the product. The materials needed for hydrogen storage should have suitable thermodynamics and kinetics for reversible hydrogen sorption and desorption. Porous carbon nanomaterials developed by Cheng *et al.* (2008) from sawdust by a carbonization and chemical activation procedure finds application as sorbents for hydrogen uptake. The experiment was carried out at different carbonization and activation temperatures. A cryogenic hydrogen uptake capacity exceeding 5 wt% at 10 bar and 2.55 wt% at 1 bar was attained with adsorption heat of 4.1–7.5 kJ/mol (Fig. 17).

Fig. 15 (a) Equilibrium adsorption isotherms of MB on the CNS before activation and activated PCNS (experimental conditions: MB concentration = 10–125 mg/L for CNS or 200–600 mg/L for PCNS, CNS or PCNS concentration = 0.5 g/L, and 30 adsorption time = 180 min), and the corresponding photos of the MB solutions before and after adsorption by (b) CNS and (c) PCNS. Reproduced from Gong, J., Liu, J., Chen, X., *et al.*, 2015. Converting real-world mixed waste plastics into porous carbon nanosheets with excellent performance in the adsorption of an organic dye from wastewater. *J. Mater. Chem. A* 3, 341–351.

It has been investigated recently, that hydrophobic electrospun carbon nanofiber fabrics (ECNFs) with the water contact angle (WCA) of $142.6 \pm 1.1^\circ$ can separate toluene and water with a separation efficiency of $>99.5\%$ within a few min with a high toluene flux of $324 \text{ L m}^{-2} \text{ h}^{-1}$ (Zhu *et al.*, 2018). High fluxes ($250\text{--}410 \text{ L m}^{-2} \text{ h}^{-1}$) were also observed with other organic solvents such as methylbenzene, ethyl acetate, tetrahydrofuran, petroleum ether, etc., demonstrating that ECNFs are promising candidates for efficient oil/water separation.

Electrocatalysis

As catalyst supports in oxygen electro reduction reactions occurring in fuel cells, the graphitic carbon nanostructures (GCN) have attracted great deal of attention. The performance of fuel cells and metal/air batteries are very much dependent on cost-effective design of electro catalysts.

The sawdust particles impregnated with Ni and Fe salts were carbonized at 900 and 1000°C, respectively to obtain GCNs and that was employed as electro-catalyst support for methanol oxidation reaction (Sevilla *et al.*, 2007). It was also used as a support for making Pt electro catalysts. Nitrogen-doped C_{60} fullerene derived from ginkgo leaves were found to be a prospective cathode catalyst for hydrogen fuel cells (Chen and King, 2005). Nitrogen-doped fullerene-like carbon shells (NDCS) synthesized from fallen ginkgo leaves via pyrolysis in N_2 was also used as an excellent ORR catalyst. The strength of planar bonds in sp^2 hybrids, its rigidity, high elastic recapture, low-friction and resistance to wear offer additional advantages for the NDCS electrode to be used in FCs under both ambient and vigorous conditions (Gao *et al.*, 2015b).

Selective catalytic reduction (SCR) of NO_x (92% NO and 8% NO_2) with NH_3 in a quartz reactor was carried out by using catalyst. The catalyst was produced by using noble metal (Pt, Ru and Pt/Ru) nanoparticles which were deposited on anthracite derived graphene sheet (GS). It was found that the PtRu/GS composite exhibited superior catalytic performance and over 90% conversion of NO at 165°C, which might have resulted from synergistic effect of Ru and Pt.

Sensing Applications

The electro-catalytic property of graphene for caffeine oxidation can be used as a biosensor and Trauzettel *et al.* (2007) could apply the biosensor to detect caffeine in the concentration range of $0.2\text{--}120 \mu\text{mol L}^{-1}$ with a limit of detection of 90 nmol L^{-1} (signal/noise = 3). Bitumen derived graphene was used as an electrode for the biosensor. Anthracite coal derived CDs was successful for Cu (II) analysis due to their selective PL quenching with Cu^{2+} ions as investigated by Hu *et al.* (2014b). The favorable response was attributed to the thermodynamic affinity of Cu^{2+} toward nitrogen and oxygen functional groups of the reduced CDs, and rapid bonding kinetics of copper. As shown in Fig. 18, the response was linear in the range of $0\text{--}0.5 \mu\text{M}$ Cu^{2+} concentration with a limit of detection 2nM and a signal/noise ratio of 3. The interaction between metal ions and reduced CDs was rapid and stabilized within 3 min. Hence, it was revealed that PL sensing had fast response and is a promising candidate for real-time Cu(II) tracking in environmental applications.

Fig. 17 Comparison of hydrogen sorption isotherms of the obtained carbons (at various carbonization temperatures labeled as BW-A, BW-B, BW-C, BW-D) activated AX-21, and multi-walled carbon nanotubes (CNT) at 196 °C over the pressure range of 0–10 bar. Up-triangles and down-triangles represent H₂ adsorption and desorption isotherms, respectively. Reproduced from Cheng, F., Liang, J., Zhao, J., Tao, Z., Chen, J., 2008. Biomass waste-derived microporous carbons with controlled texture and enhanced hydrogen uptake. *Chem. Mater.* 20, 1889–1895.

Biomedical Applications

Graphene oxide extracted from low grade coal was found to be a potentially suitable vehicle for drug delivery (Pakhira *et al.*, 2015). A GO-DL (donepezil) composite encapsulated with GO was successfully used in the treatment of mild to moderate Alzheimer's disease. The drug molecules were stably entrapped inside the clenched fist of GO in an acidic environment of pH 6.8 but at an alkaline environment of pH 7.4 would trigger the release of DL. Thus, the DL drug could be effectively delivered by closed fist shapes of coal-derived GO with its release depending on pH. The metal contaminants in coal and the difficulty with the removal of acidic species from the synthesized carbon based nanomaterials lower their biocompatibility, which limits their potential application in biomedicine. By encapsulating the CDs in liposomes for in vitro and in vivo bio-imaging applications Geng *et al.* (2017) managed to improve the bio-compatibility of coal-derived carbon quantum dots. The liposome-CD composite was shown to exhibit low cytotoxicity with HeLa cells having viability above 92% after incubation over one day.

Energy Storage

There is an increasing mandate to develop new renewable technologies to meet the increasing energy demands. As an energy storage device, supercapacitors are getting more attention than batteries because of power density, good reversibility and long cycle life (Miller and Simon, 2008). The electrochemical performance of supercapacitor electrode is explored with carbon nanomaterials which are synthesized from biomass (Genovesea *et al.*, 2015). Corn cob (Genovesea *et al.*, 2015), waste coffee ground (Yun *et al.*, 2015), water melon (Wu *et al.*, 2013), hemp fiber (Wang *et al.*, 2013b) have been used to produce supercapacitor based electrodes. The biomass was used to synthesize NCTs, CNS based supercapacitors, and all of them exhibited excellent capacitance value with good electrical transport properties. It was found that biochar electrode produced from corn cob was extremely robust even after 5000 successive cycles, showing only a 3% fading capacitance (Ravi and Vadukumpully, 2016). These behaviors undoubtedly project that the materials are to possess high power-energy characteristics. At a high power density of 20 kW/kg and at 20, 60 and 100 °C, the energy density values were 19, 34, and 40 Wh/kg, respectively (Fig. 19). Thus these high performance carbon nanostructures are promising candidates for usage as electrodes in energy storage devices.

Fig. 18 The dependence of F/F_0 on the concentration of Cu^{2+} in a range of 0–50 μM . Inset shows the corresponding fluorescence response of r-CDs dispersion upon addition of various concentration of Cu^{2+} . Reproduced from Hu, C., Yu, C., Li, M., *et al.*, 2014b. Chemically tailoring coal to fluorescent carbon dots with tuned size and their capacity for Cu(II) detection. Small 10, 4926–4933.

Carbon nanomaterials derived from cost effective sources can act as anode material for Li-ion batteries. Zhang *et al.* reported that rice straw is a good source of carbon nanomaterials to be used as anode in Li-ion battery application (Zhang *et al.*, 2009). The presence of microspores is the limitation and carbon nanostructures alone are not adequate to get good rate of performance at a high current density.

A simplistic and economical route for the preparation of a graphitic material from spongy pomelo peels (SPP) was explored which was found to be an effective anode material for Li ion batteries (Sun *et al.*, 2013). As an anode material, it showed high capacity, outstanding cycling stability and rate capability with a high capacity value of 452 mAh/g at a current density of 90 mA/g and it was retained even after 200 cycles (Fig. 20).

Coal derived carbon nanomaterials are also used in energy applications in Li-ion batteries. CNTs from bitumite coal (Li *et al.*, 2017), N, S-codoped CNTs (Liu *et al.*, 2015a), coal derived graphene/ Mn_3O_4 composite (Gao *et al.*, 2014), 3D hollow porous graphene balls (HPGBS) from coal tar, PAN and coal derived carbon nanofibers (PAN-coal-CFs) (He *et al.*, 2014), bituminous coal derived GQDs (Zhang *et al.*, 2017d) have exhibited high performance as supercapacitor electrode.

Zhang *et al.* (2017d) prepared a high performance supercapacitor electrode based on activated hierarchical porous carbon nanosheets (HPCNs) from bituminous coal-derived GQDs. When the current density increased from 1 to 100 A g^{-1} , the specific capacitance decreased from 230 to 170 F g^{-1} that is by only 26%, implying a superior rate capability of the activated HPCNs. Moreover, the material demonstrated an excellent durability with no obvious fading in specific capacitance after 10,000 galvanostatic charge/discharge cycles at a current density of 10 A g^{-1} . Good electronic conductivity, high surface area ($1450 \text{ m}^2 \text{ g}^{-1}$) and micro/mesoporous distribution in activated HPCNs might be providing more active sites for energy storage and more channels for ionic transport. Meanwhile, a report presented by Guo *et al.* (2017a) used coal based hierarchical porous carbon spheres (PCS) as an electrode active material for supercapacitors. They found that CV plots were in a quasi-rectangular shape with a broad peak between 0.2 and 0.8 V, which was attributed to the surface oxygen pseudo-capacitance. The material exhibited a high specific capacitance of 227 F g^{-1} at 1 A g^{-1} and superior cycle stability in 6 M KOH after 10,000 charge/discharge cycles at 2 A g^{-1} . In addition, a symmetrical device based PCS showed a specific capacitance of 180 F g^{-1} at 0.2 A g^{-1} , which remained at 112 F g^{-1} at 5 A g^{-1} , indicating an excellent rate capability.

Other Nanomaterials for Energy Storage

The energy and environmental crisis is a factor of great concern for sustainable development of human society. Electrochemical energy storage and conversion devices (EESCDs) are emerging as primary power sources for global efforts to shift energy dependence from limited fossil fuels towards sustainable and renewable sources. EESCDs including lithium ion batteries, supercapacitors, alkali ion batteries, alkaline batteries, and photo-electrochemical devices are promising for their high energy or power densities, portability, and long cycle life. However, the promise is often overshadowed by greater surface area and higher reactivity of nanostructured active materials and manufacturing limitations (Zhua *et al.*, 2017; Share *et al.*, 2016). Therefore, electrode materials and components must be appropriately designed and synthesized to enhance the kinetics of ion and electron transport to achieve high-performance EESCDs. In the following sections recent advances in EESCDs, new synthesis approach and control of surface properties are discussed.

Lithium Ion Batteries (LIBs)

Though there is great advancement of LIBs as energy storage devices since 1990s, but till now it is facing great limitations due to limited capacity of electrodes (anode and cathode). Commercial graphite is used as anode materials but it suffers from relatively

Fig. 19 (a) CV curves of CNS-800 for three different scan rates, tested at 2 °C; (b) galvanostatic charge/discharge profiles of CNS at a current density of 10 A/g; (c) Nyquist plots and (d) frequency responses of CNS measured at 0, 20, 60 and 100 °C. Fig. 20 Rate capability of the carbon at different rates: (i) 40, (ii) 80, (iii) 160, (iv) 320, (v) 40 mA/g, respectively. Reproduced from Sun, X., Wang, X., Feng, N., *et al.*, 2013. A new carbonaceous material derived from biomass source peels as an improved anode for lithium ion batteries. *J. Anal. Appl. Pyrolysis* 100, 181–185.

low capacity. Lithium titanate (LTO), is a typical alternative high rate anode, but the electronic and ionic conductivities are not satisfactory. [Saxena and Sil \(2017\)](#) reported vanadium doped $\text{Li}_4\text{Ti}_5\text{O}_{12}$ (LTO) with enhanced high-rate performance and ion transfer at high working current. [Pan et al. \(2017\)](#) designed integrated graphene foam LTO anode which greatly reinforced the discharge capacity and power density. The LTO based anode showed excellent high-rate capability, about 10 times larger than the commercial graphite, up to 50–200°C. But the higher working voltage in the voltage range of (1–2 V versus Li^+/Li), and lower discharge capacity of LTO ($< 200 \text{ mAh g}^{-1}$) which is higher than the commercial graphite, would result energy and power loss when coupled with the commercial cathode. Hence, the searches for anode for LIBs are still going on.

Silicon based materials are one of the promising successor to commercial graphite as it demonstrated ultrahigh theoretical specific capacity (4200 mAh g^{-1}) and low working potential (0.5 versus Li^+/Li) but due to huge volumetric expansion ($> 300\%$) the columbic efficiency and cyclic life are poor. Moreover, it also exhibits poor electrical conductivity. Biomass derived carbon/silicon three dimensional hierarchical composite or Si as an additive for carbon or graphite anode can enhance the performance of anode remarkably ([Shen et al., 2017b](#)). Exploration with metal oxides such as NiO , MoO_2 and MoO_3 has been widely done by Tarascon group ([Poizot et al., 2001](#)). These metal oxides suffer from some common issues such as poor cycling stability due to large volume and embarrassingly high working voltage which is above 1 V.

Exploration with the cathode is also going on. Tarascon group reported that by doubling the capacity of cathode, the energy density could be increased by 57%, whereas only an increase of 47% can be achieved increasing the capacity of anode by a factor of 10 ([Tarascon, 2010](#)). [Chen et al. \(2017a\)](#) have demonstrated that surface coating of layered $\text{LiNi}_x\text{Co}_y\text{Mn}_z\text{O}_2$ for LIBs could improve the capacity significantly for commercial LIBs. But the cycling life should be further enhanced by introduction of different surface coating with the aid of multiscale design. On the other hand, [Cao et al. \(2017\)](#) and [Mao et al. \(2017\)](#) adopted porous design strategy to construct N doped carbon/ LiFePO_4 microspheres and LiMn_2O_4 hollow microspheres as high-performance cathode, respectively. Though the porous design will decrease the tap density of active materials, the transfer kinetics of ions/electrons would be greatly accelerated leading to enhanced high-rate performance.

High Performance Post Lithium Ion Batteries

The high cost and scarcity of lithium have spur in full swing, the search on alternatives to lithium. Sodium ion batteries (SIBs), potassium ion batteries (PIBs), and magnesium ion batteries (MIBs) due to their cost-effective, non-toxic, and larger reserves on earth (about one thousand times more abundant than lithium) are entering into the vision of researchers. Though the performance does not match yet the LIBs, the researchers are optimistic on improvement and these are the hotspots of research ([Chang et al., 2017](#); [Cho et al., 2017](#)).

High Performance Supercapacitors

The higher surface area makes supercapacitor an attractive power solution for an increasing number of applications. [Guo et al. \(2017b\)](#) presented hierarchical $\text{Co}_3\text{O}_4@\text{PPy}$ core-shell composite nanowires for supercapacitors with enhanced electrochemical performance. [Lu et al. \(2017\)](#) reported Bi_2S_3 nanoparticles anchored on graphene nanosheets with superior capacitive performance. The PPy shell and graphene matrix can enhance the electrical conductivity and structural stability, resulting in enhanced capacitance. [Xie et al. \(2017\)](#) designed negative electrode of $\text{Fe}_2\text{O}_3/\text{graphene oxide}$ paper for high energy supercapacitors. Moreover, MnO_2 based cathode such as nanotubes and nanowires are discussed by [Xiao et al. \(2017\)](#) and Kim group ([Tran et al., 2017](#)). It is proven that nano-structuring on MnO_2 is favorable for the fast transportation of ions/electrons, leading to increased utilization of active MnO_2 . However, till to date, the working mechanism on the pseudo capacitive materials is still not clear and controversial.

High Performance Alkaline Batteries

Hybrid alkaline batteries are getting attention as one of the promising energy storage devices as they use battery-type cathode and capacitor-type anode, hence, utilizing the combined advantages of batteries (high energy density) and capacitor (superior power density). Extensive theoretical and experimental studies have demonstrated that the performance of alkaline batteries is mainly determined by the electrochemical activity and kinetic feature of electrodes. [Wu et al. \(2017\)](#), [Chen et al. \(2017b\)](#) and [Ma et al. \(2017\)](#) reported Ni nanoparticles embedded into cross-linked NiO nanoflakes as enhanced cathode, cobalt oxide nanoflakes grown on cobalt nanowires and nickel hydroxide shell on TiO_2 nanorod for alkaline batteries as cathode respectively. These arrays architecture offers shortened ion diffusion paths and facilitates migration of the electrolyte ions, leading to improve high-rate performance. It is noteworthy that these metal oxides/hydroxides cathode must be coupled with capacitive carbon anode to achieve high performance.

High Performance Optical-Electrochemical Energy Storage and Conversion

Solar energy is a clean, abundant and unlimited source of energy which can meet the global energy demand in a green way ([Shen et al., 2017a](#)). It has a wide spectrum of applications of which solar heating, photovoltaics, photo-electrochemical water splitting,

photosynthesis, and photocatalysis are to be mentioned. Shi *et al.* (2017), Zhang *et al.* (2017b), Yadian *et al.* (2017), and Railey *et al.* (2017) have reported the improvements of phototransistors, photocatalytic and photo electrochemical performance respectively with different nanomaterials. These results show that the interface structure is very important to the high absorption/utilization of light energy. All the results indicate that the design/fabrication of interface structure or active materials should be combined with the theoretical calculation results, which can guide the synthesis of efficient photo-electrochemical catalysts and photo anode/photocathode.

3D Printed Nanomaterials for Energy Storage

The micro-sized electrochemical energy storage (EES) devices have customized configurations for easy integration into other micro-electronics (Gogotsi and Simon, 2011; Wang *et al.*, 2014). These configurations must have ultrahigh resolution to shorten transport distances and at the same time should provide sufficient active material to ensure adequate energy output for an extended timeframe. Building of thicker electrodes is the key to further improve the areal capacitance and energy density without sacrificing fast ion diffusion. However, thicker electrodes are associated with reduction of rate capability as the electron transport distances increase with overall increased electrical resistance of electrode. Therefore, fabrication of electrodes or devices involving micro-, meso- and macro-pores via a controllable and scalable method remains a significant challenge (Beidaghi and Gogotsi, 2014). Additive manufacturing (AM) refers to an industrial production technique whereby, 3D objects are created by adding layer-upon-layer of material directly from computer-aid-design (CAD) files. This method is also known as 3D printing which offers the freedom to fast create complex architectures at lower cost than conventional subtractive methods (Gibson *et al.*, 2010). The 3D printing techniques can be divided into several categories: laser deposition of energy fusible powders, photo-polymerization of ultra-violet (UV) sensitive liquids, electrodeposition of surface charged particle-based suspensions, and extrusion deposition of colloidal gels (Gibson *et al.*, 2010; Duoss *et al.*, 2014). Recently, a couple of these 3D printing methods have been applied for electrochemical or energy-related applications (Ambrosi and Pummera, 2016; Fu *et al.*, 2016; Tian *et al.*, 2017), a few of which are discussed in the subsequent paragraphs.

Laser-Based 3D Printing for EES

Laser can consistently and precisely deliver high thermal energy to a target using a highly collimated, coherent beam of light. In a laser-based printing process, the irradiation instantly melts, sinters or chemically converts functional materials into diverse micro-patterns (Gu *et al.*, 2012; Gu, 2015a; Sokolov *et al.*, 2010). Any thermally fusible powder materials can be directly used for laser printing. This is a single-step non-contact and mask-free fabrication which obviates the need for costly, time-consuming, and labor-intensive lithography and related post-processing operations (Gu, 2015b). Laser-based 3D printing has two unique features: (i) a wide selection of materials such as polymers, ceramics, and metals can be made; (ii) no complicated material processing techniques are needed. These advantages make laser-based printing a preferred technique for rapid prototyping of on-chip EES micro-devices (El-Kady *et al.*, 2012; El-Kady and Kaner, 2013; El-Kady *et al.*, 2015; Lin *et al.*, 2014; Li *et al.*, 2016).

Selective Laser Melting

Selective laser melting (SLM) is a specific 3D printing technique, which facilitates specific functions and properties. Near net-shape parts with near full density (up to 99.9% relative density) can be achieved by utilizing high power-density laser. Layer-by-layer scanning and fusion powders are carried on depending on the pre-designed patterns (Fig. 21(a)) (Gao *et al.*, 2011). Ambrosi *et al.* printed helical shaped steel electrodes using SLM (Fig. 21(b)) (Yap *et al.*, 2015). These tailor-made stainless steel electrodes were used as platforms for supercapacitors, catalysts and sensors by means of an effective and controlled deposition of iridium dioxide (IrO₂) films (Fig. 21(c)) which demonstrated excellent capacitive and catalytic properties in alkaline solutions and Nernstian behavior as potentiometric pH sensors.

Direct Metal Laser Sintering

Direct metal laser sintering (DMLS) is another 3D metal printing method, used to build objects out of almost any metal alloy (Ambrosi *et al.*, 2016). In this technique a precise, high-wattage laser is used to micro-weld powdered metals. Objects free from residual stress can be produced by this method.

Template-Assisted Electrodeposition

To obtain electrodes with more complex microstructures, electrodeposition is frequently combined with pre-engineered templates to tune the morphology and structure of deposited films. The 3D ultrafast graphene and silicon (Si) battery electrodes were fabricated by combining electrodeposition with a traditional templating method as mentioned by Zhang *et al.* (2011) and

Fig. 21 (a) Schematic illustration of SLM process. (i) High-power laser melts selective areas of the powder bed. (ii) Process is repeated for successive layers. Review of selective laser melting: Materials and applications. *Appl. Phys. Rev.* 2, 041101.

(Zhang and Braun, 2012). As a result rapid ion transport, a short solid-phase ion diffusion length, a large electrode surface area and high electron conductivity were achieved. The schematic of the process is outlined in Fig. 22.

Ultrahigh charge and discharge rates with minimal capacity loss were obtained from the printed device. Rates of up to 400 C and 1000 C for lithium-ion and nickel-metal hydride chemistry, respectively, were achieved (1C rate refers to a current density that can fully charge or discharge a battery in one hour), enabling fabrication of a lithium-ion battery that can be 90% charged in two minutes. Pikul *et al.* (2013) have also achieved similar results by assembling the electrodes into interdigitated 3D lithium ion batteries.

Surface Engineering for Energy Storage Device

In surface engineering the properties of surface is engineered separately from the bulk material to harness the true application potential of heterogeneous material systems. It is a critical component in energy storage applications to design functional electrode with nanomaterials. Commercial scale batteries still use micro-scale materials for electrodes, which may be due to (i) manufacturing challenges of nanomaterials and (ii) the reactive nature of nanoscale materials. Armand and Tarascon (2008). In Fig. 23, control of properties of nanomaterials through surface engineering is presented.

New nanoscale materials have better performance compared to bulk materials but at cell-level the performance is reduced due to consumption of increased electrolyte while forming a stable electrode-electrolyte interface. In energy storage devices, a stable electrode-electrolyte interface is required to prevent Faradic charge transfer reaction and sustain an electric double layer. Moreover, Faradic charge transfer reaction must store and release energy without degradation (Share *et al.*, 2016). Surface engineering offers the scope to identify a material with ideal bulk properties and then independently engineer the surface properties to be stable. A few common surface engineering techniques are highlighted below.

Chemical Vapor Deposition and Atomic Layer Deposition

Chemical vapor deposition (CVD) and atomic layer deposition (ALD) are two processes where the materials in gas phase are used for surface engineering. In CVD the reactions between the gas phase precursor and the substrate are controlled by the precursor partial pressure, the temperature, and the reactivity of the electrode. In ALD the precursors react in a self-limiting process enabling atomic-level control where the alternate pulsing of two or more precursors is needed.

Fig. 22 (a) Schematic of the printed battery with a cathode equipped with a bi-continuous pathway for ions and electrons. (b) Illustration of the four primary resistances in a battery electrode: (1) Ion transport in the electrolyte, (2) ion transport in the electrode, (3) electrochemical reactions in the electrode, and (4) electron conduction in the electrode and current collector. (c) Bi-continuous electrode fabrication process: The electrolytically active phase is yellow and the porous metal current collector is green. The electrolyte fills the remaining pores. Fig. 23 Schematic representing the different properties of nanostructures that can be controlled through surface engineering. Reproduced from Share, K., Westover, A., Li, M., Pint, C.L., 2016. Surface engineering of nanomaterials for improved energy storage – A review. *Chem. Eng. Sci.* 154, 3–19.

Though CVD is a promising method to engineer the physical, chemical, and mechanical properties of surfaces, precise thickness control can be difficult to achieve. Carbon nanomaterials deposited by CVD on various substrates could improve certain properties of substrate like conductivity (Su *et al.*, 2011), mechanical properties (Taylor, 1991), hydrophobicity (Liu *et al.*, 2004). But the use of high temperatures in CVD process can damage or decompose some materials and limits the choice of stable precursors. Hence, various techniques are employed in CVD to overcome the limitations (Chhowalla *et al.*, 2001). ALD involves a two-step process with an organometallic Precursor and an oxidizing or reducing agent. Inert gas, such as Ar or N₂, carries away the unreacted

residual precursor molecules to avoid a CVD reaction between precursors. Compared to CVD, ALD provides more precise thickness control and can be operated at much lower temperatures. However, only limited materials can be deposited by ALD process mainly because of the high requirement of the precursor, which should have a self-limiting reaction and be volatile.

Mechanism of Surface Engineering for Energy Storage Materials

Surface Engineering has become a critical aspect to design electrodes with nanomaterials for energy storage. By surface engineering the favorable condition of both the bulk materials and electrochemical interphase of electrolyte and bulk materials can be utilized. The complexity of the engineering challenge can be dramatically decreased by utilizing surface engineering which allows a researcher to identify a material with ideal bulk properties, and then independently engineer the surface properties to be stable. In the following section the mechanism of surface engineering is discussed briefly.

Chemical Activation

Pseudocapacitive electrodes and battery electrodes are two different types of energy storage devices. The surface area, electrical conductivity, and/or ionic transport play an important role to engineer independently physical properties and electrochemical properties of the template.

Hybrid supercapacitors and pseudocapacitors

Pseudocapacitors and hybrid supercapacitors are based on a form of Faradaic storage that involves faster charging and discharging rates than typical batteries. A pseudocapacitor can store over a range of voltages instead of at a fixed redox couple like a battery. Ni(OH)₂, cobalt oxides, mixed metal oxides, or organic materials, are hybrid supercapacitors electrodes, while common pseudocapacitor electrodes are MnO₂ and RuO₂ (Share *et al.*, 2016).

Common processing techniques for depositing the faradaic material have advantages and disadvantages but conformal and complete coatings of the substrate by the active material can mitigate capacity fade during cycling (Zilong *et al.*, 2014). Zilong *et al.* (2014) electrodeposited a conformal coating of MnO₂ onto ZnO NWs that was less than 5 nm thick and were able to achieve over 5000 cycles with only 1.5% loss in capacitance.

Separate processing of substrate and surface can optimize the use of active materials during deposition as reported by Ke *et al.* (2015). They investigated TiO₂ NW arrays but with a TiO₂/Ni(OH)₂ core shell as shown in Fig. 24.

Fig. 24 SEM images of (a) A-3/CFP, (b) A-4/CFP, (c) A-6/CFP and the insets show the high magnified SEM images of Ni(OH)₂, (d) Schematic diagram showing the Ni(OH)₂ nanowalls growth process, (e) CV curves ranging from 0.2 to 0.6 V at a scan rate of 5 mV s⁻¹, (f) Capacity at different current densities.

The $\text{Ni}(\text{OH})_2$ morphology, crystallinity and surface area were optimized during chemical bath deposition process where different amount of ammonia was used. Less ammonia was beneficial in achieving thinner nanowalls with higher surface area but with higher capacities and lower charge transfer resistance. Thus TiO_2 scaffold provided a 3D nanostructure with efficient electron transport while $\text{Ni}(\text{OH})_2$ acted as the optimized active material. This approach was found to be beneficial for graphene and other conductive carbon substrates with a high surface area and the capacitance was increased by $\sim 20\%$ (Share *et al.*, 2016).

Batteries

Batteries are generally optimized for total storage capacity instead of power capacity. Unlike pseudocapacitors, redox reactions in batteries access deep bulk material and not just the surface. Hence, there is a large volume expansion of the electrode. During charging and discharging of batteries solid electrolyte interphase (SEI) is formed, where high surface area is not necessary.

Metal oxides and sulfides like TiO_2 , V_2O_5 , and Cu_2S can be used as active layers in traditional ALD but recent work has focused on lithiated electrode materials such as LiCoO_2 , LiMn_2O_4 , and LiFePO_4 (Share *et al.*, 2016).

Electrode architecture and electrode thickness both can limit the performance, emphasizing the importance of separate optimization. TiO_2 nanotubes with varying aspect ratio but of same surface area were fabricated and it was found that higher aspect ratios have higher capacities, especially at fast rates (30C), due to better electron/ion transport. Some researchers used anodic alumina templates and compared that with a 3D NW template on a Ni current collector with ALD deposited TiO_2 (Fig. 25) (Share *et al.*, 2016).

Due to the unique template, multiple interconnects were formed in the 3D NW network, and thus agglomeration of the NWs was prevented resulting in much higher real capacities and rate capabilities. The TiO_2 thickness was varied during ALD deposition where an 8 nm film had a higher capacity and better rate capability than a 16 nm.

Multi-valent ion batteries such as Al^{3+} and Mg^{2+} bring potential for high capacity batteries. However, due to multivalent state of the ions, the diffusion of these ions through electrodes is particularly limited. Designing electrodes with short diffusion lengths are important to achieve good rate capability, which emphasize the importance of chemical activation process. NW arrays of V_2O_5 and TiO_2 have shown promise as Al ion electrodes. These newer battery technologies still suffer from irreversible reactions between the electrolyte and electrode/current collector but by using techniques discussed earlier could mitigate these issues (Share *et al.*, 2016).

Fig. 25 (a) Schematic fabrication process flow for straight Ni/TiO_2 nanowire arrays (top) and 3D Ni/TiO_2 nanowire network (bottom), which uses Al foils with different impurity. The side holes in the 3D PAA template result in interconnections in 3D nanowire network. (b) Rate capabilities of 32 μm long 3D Ni/TiO_2 nanowire network structure with different TiO_2 coating thicknesses. (c) SEM images of Straight Ni/TiO_2 nanowire arrays and (d) as-prepared 3D Ni/TiO_2 nanowire network.

Conclusions

In this paper the synthesis of nanomaterials is reviewed with a close focus on production of CNMs from different types of coals and sustainable resources through wide range of fabrication routes. An insight on potential applications of CNMs is also provided. The key challenge is to produce high quality CNMs in large scale without causing any major environmental concern, while ensuring better yield and performance. Though coal is mainly used for thermal power generation, coal-based NMs can be harnessed for sustainable energy generation and environmental remediation through electrocatalysis, separation of components through efficient adsorption and in sensing applications. However, care should be taken so that sustainable coal sources do not interfere with food chain. CNMs have potential application as energy storage device. In this regard different active materials of EES including LIBs, SIBs, MIBs, post-LIBs, supercapacitors and their merits and demerits are also highlighted. Though the current LIBs and supercapacitors are still flourishing but their potential alternatives using NMs and nanotechnology are emerging. However, challenges associated with incorporation of nanostructure into high performance EES devices need to be addressed. These challenges can be handled by incorporating 3D printing manufacturing and surface engineering. Surface engineering can be the most relevant theme in energy storage device with respect to cathode design for LIS batteries, dendrite migration in metal anode, and micro-crack prevention in high voltage cathodes. Atomic layer deposition will enable a limitless area of innovation for next generation energy storage technology. Moreover, modifying the surface independently from the bulk materials can add another dimension to unlock the promise of future advance in energy storage systems. Though 3D printing offers tremendous flexibility, there are few limitations with this process in the context of versatility and customizability. But it is envisioned that with the current efforts for continuous development of 3D printing techniques aimed at offering high-speed, low-cost versatile production capability and resolution, 3D printing will eventually become an essential part of future EES manufacturing.

Nano-Porous Materials for Energy Conversion Using Green Technologies

Salah A Elsheikhi and Khaled A Eldressi, University of Benghazi, Benghazi, Libya

© 2020 Elsevier Inc. All rights reserved.

Introduction

One of the great challenges in the recent years is unquestionably energy conversion. In response to the recent needs of the world, it is now necessary that new, low-cost and environmentally friendly energy conversion systems are found; hence the accelerating of the development of research in this area. Nanomaterial lies at the heart of the advances that have already been made in energy conversion. Nano materials have various morphology structures based on their structural complexity. [Fig. 1](#) shows nanostructured materials with different morphologies ([Kumar et al., 2017](#)).

Dimensionality of Nanoparticles

They are generally classified based on their dimensionality, morphology, composition, uniformity, and agglomeration.

1D nanomaterials

These are one dimensional in the nanometer scale are typically thin films or surface coatings, and include the circuitry of computer chips and the antireflection and hard coatings on eyeglasses. These have been used in electronics, chemistry, and engineering ([Kumar et al., 2017](#)).

2D nanomaterials

Two-dimensional nanomaterials have two dimensions in the nanometer scale. These include 2D nanostructured films, with nanostructures firmly attached to a substrate, or nanopore filters used for small particle separation and filtration. Asbestos fibers are an example of 2D nanoparticles ([Kumar et al., 2017](#)).

3D nanomaterials

Materials that are nanoscaled in all three dimensions are considered 3D nanomaterials. These include thin films deposited under conditions that generate atomic-scale porosity, colloids, and free nanoparticles with various morphologies ([Kumar et al., 2017](#)).

Porous and Porous Material

Nano-porous materials as a subset of nanostructured materials possess unique surface, structural, and bulk properties that underline their important uses in various fields such as ion exchange, separation, catalysis, sensor, biological molecular isolation, and purifications. Nano-porous materials are also of scientific and technological importance because of their vast ability to adsorb, and interact with atoms, ions, and molecules on their large interior surfaces and in the nano-meter sized pore space.

The presence of pores (holes) in a material can render itself all sorts of useful properties that the corresponding bulk material would not have ([Kresge et al., 1992](#)). Pores are categorized into two types: open pores which connect to the surface of the material and closed pores which are isolated from the outside as shown in [Fig. 2](#).

In [Fig. 2](#), region 'a' represents the closed pores, and regions such as b, c, d, e, and f represent open pores ([Ishizaki et al., 1998](#)).

In functional applications such as adsorption, catalysis, and sensing, closed pores are not of any use. In separation, catalysis, filtration or membranes, often penetrating open pores are required. Materials with closed pores are useful in sonic and thermal insulation, or lightweight structural applications. Pores have various shapes and morphology such as cylindrical, spherical and slit types. There are also pores taking more complex shapes such a hexagonal shape. Pores can be straight or curved or with many turns and twists thus having a high tortuosity ([Shirosaki et al., 2016](#)). Based on the International Union of Pure and Applied Chemistry (IUPAC) the pore size is classified into three types: less than 2 nanometers in diameter (micropores), between 2 and 50 nanometers (mesopores) and more than 50 nanometers (macropores) as shown in [Fig. 3](#) ([Shirosaki et al., 2016](#)).

Nanoporous materials are a subset of porous materials, typically having large porosities (greater than 0.4), and pore diameters between 1 and 100 nanometers. In the field of chemical functional porous materials, it is better to use the term "nanoporous" consistently to refer to this class of porous materials having diameters between 1 and 100 nm. For most functional applications, pore sizes normally do not exceed 100 nanometers anyway ([Lu and Zhao, 2004](#)).

Nanoporous materials classification

Porous materials can be classified according to their materials constituents (such as organic or inorganic; ceramic or metal) or their properties. [Table 1](#) summarizes the available nanoporous materials according to their chemical compositions and their technical characteristics ([Lu and Zhao, 2004](#)).

Major applications of nanoporous materials

The applications of the nanoporous materials have not limited to the traditional areas of adsorption separation, catalysis, and membranes; but in the recent years they have expanded into promising applications, which can be summarized as follows (Lu and Zhao, 2004):

- Environmental separations.
- Clean energy production and storage.

Fig. 3 IUPAC classification of pores. Reproduced from Shirosaki, Y., Nakamura, Y., Yoshioka, T., Osaka, A., 2016. Inorganic-organic hybrids for biomedical applications. In: Klein, L., Aparicio, M., Jitianu, A. (Eds), Handbook of Sol-Gel Science and Technology. Springer: Cham.

Table 1 Nanoporous materials classification

	<i>Polymeric</i>	<i>Carbon</i>	<i>Glass</i>	<i>Alumino-silicate</i>	<i>Oxides</i>	<i>Metal</i>
Pore size	Meso- macro	Micro- meso	Meso- macro	Micro- meso	Micro- meso	Meso- macro
Surface area/Porosity	Low > 0.6	High 0.3–0.6	Low 0.3–0.6	High 0.3–0.7	Medium 0.3–0.6	Low 0.1–0.7
Permeability	Low-medium	Low-medium	High	Low	Low-medium	High
Strength	Medium	Low	Strong	Weak	Weak-medium	Strong
Thermal stability	Low	High	Good	Medium-high	Medium-high	High
Chemical stability	Low- medium	High	High	High	Very high	High
Costs	Low	High	High	Low- medium	Medium	Medium
Life	Short	Long	Long	Medium- long	Long	Long

Note: Lu, G.Q., Zhao, X.S., 2004. Nanoporous Materials: Science and Engineering. Imperial College Press, p. 4. (ISBN: 1-86094-210-5).

- Catalysis and photocatalysis.
- Sensors and actuators.
- Biological applications.
- High-efficiency filtration and separation membranes.
- Catalytic membranes for chemical processes.
- Porous electrodes for fuel cells.
- High-efficiency thermal insulators.
- Electrode materials for batteries.
- Porous electronic substrates for high-speed electronics.

These applications can be summarized in [Table 2](#) ([Sun et al., 2016](#)).

Energy Conversion

Energy conversion concerns the transformation of energy from one form to another, for example, sunlight to chemicals or electricity, electricity to thermal and mechanical energy, chemicals to thermal energy and electricity. Today the sense of energy conversion deals with the conversion of one form of energy to that we can use directly. Energy conversion is a very hot topic and essential to nature and the human society.

Nanoporous materials have played an important role in energy-related applications such as catalysts, and solar energy conversion and chemical energy conversion ([Sun et al., 2016](#)). As one of the clean energy sources with the best potential, solar energy conversion devices, which include commercial silicon solar cells, organic solar cells, quantum dot solar cells, DSSCs, photo-synthetic solar cells, and photocatalytic water splitting systems, have been well studied ([Mor et al., 2006](#); [Liu et al., 1998](#); [Keis et al., 2002](#); [Tennakone et al., 1995](#); [Chappel and Zaban, 2002](#); [Gebeyehu et al., 2001](#); [Reijnen et al., 2002](#); [Sun et al., 2016](#)). Fuel cells (FCs), another potential clean energy sources, have also been widely investigated as chemical energy conversion systems. Considering that there have been many interesting reviews on solar energy conversion, this section only pays attention to the recent progress in typical porous structures for different types of solar cells. The reviews will also focus on the recent developments on fuel cells applications.

Solar Energy

Solar energy is well recognized as one of the most promising choices to meet the predicted energy demand in the near future. This has inspired advances in solar cell research in an attempt to improve the direct conversion of solar radiation energy into electricity. It can be used efficiently in various practical applications like solar power plants, solar cell, seawater desalination, solar collectors, etc. In fact, sunlight falling on Earth offers a solution, since the hourly solar flux incident on Earth's surface is greater than the

Table 2 Applications of hierarchically structured porous materials in energy conversion and storage, photocatalysis, catalysis, adsorption, separation, sensing, and biomedicine

Applications		Types	Structural properties	Positive effects in applications
Energy conversion and storage	Energy conversion	DSSCs Fuel cells	(i) Porous hierarchy	(i) Efficient light-harvesting, especially in biomaterials replica or biocomposites;
		Photocatalytic hydrogen production	(ii) High surface area;	(ii) Fast charge separation and high current density;
	Energy storage	Supercapacitors	(iii) Short diffusion length	(iii) High gas permeability;
		Lithium-ion batteries		(iv) High storage density;
		Lithium-sulfur batteries		(v) Fast electron and ion transport;
		Lithium-air batteries		(vi) Small resistance
		Sodium-ion batteries		
		Magnesium-ion batteries		
Catalysis and photocatalysis	Photocatalysis	Metal catalysts metal oxide catalysts zeolites	(i) Porous hierarchy	(i) High accessibility of bulky molecules;
	traditional catalysis	metals loaded on hierarchically porous inert supports	(ii) High surface area;	(ii) High diffusion rate of reactant and product;
			(iii) Tunable pore size	(iii) Usually, heteroatoms of zeolites or supported nanometal particles as active sites
			(iv) Large pore volume	
Adsorption and separation		Adsorption separation	(i) Homogeneous flow-through pore structure;	(i) High permeability;
			(ii) High surface area;	(ii) Usually, monolithic column used
			(iii) Controlled pore structures and surface properties;	
Sensing		ZnO-based sensors other metal/bimetal oxide based sensors graphene-based sensors	(i) Porous hierarchy	(i) Large surface adsorption positions and reacting areas;
			(ii) High surface area;	(ii) Facile gas diffusion and mass transport
			(iii) Short diffusion length	
Biomedicine		Bone tissue engineering	(i) Porous hierarchy	(i) Improved bioactive behavior and easy for cell penetration, tissue ingrowth;
			(ii) High surface area;	(ii) Enhanced drug diffusion, loading and release;
			(iii) Large pore volume	(iii) High enzyme loadings and quick enzyme immobilization rates

Note: Sun, M.-H., Huang, S.-Z., Chen, L.-H., *et al.*, 2016. Applications of hierarchically structured porous materials from energy storage and conversion, catalysis, photocatalysis, adsorption, separation, and sensing to biomedicine. *The Royal Society of Chemistry* 45, 3479–3563. doi: 10.1039/c6cs00135a.

annual human consumption of energy in a year (Hussein, 2015). That is why the sun so appears in gas an ultimate energy source on the earth. The quantity of solar energy received by the earth is a function of the season, with the highest quantity of incoming solar energy received during the summer months (Hussein, 2015). The big challenge in using these devices is that the clear weakness in the absorption properties of the conventional fluids which lead to reduce the efficiency of these devices. Nowadays, this problem can be solved easily and effectively by using the concept of nanotechnology. The increased surface area to volume ratio of nanoparticles should enhance solar energy collection and efficiency by exposing more conducting surfaces to the sunlight. Another area that nanotechnology will increase solar cell efficiency is by using materials like lead-selenide. These materials cause more electrons (and therefore more electricity) to be released when hit by a photon of light (Hussein, 2015).

Furthermore, the cost is a major factor in the success of any solar technology. Because converting solar energy into electricity occurs at a price comparable with fossil fuel. Semiconductor materials that exhibit a photovoltaic (PV) effect can be used to convert solar radiation into electricity through a photovoltaic process. Photo-voltaics are surfaces typically consisting of a conducting oxide layer and a catalytic platinum layer that directly convert sunlight to electrical energy. A device which converts photons from the solar light into electricity using electrons is called the photovoltaic solar cell. Solar energy is very environment-friendly. For example, if a distributed solar grid meets 1% of the world's electricity demands, approximately 40 million tons of carbon dioxide

Fig. 4 The major ways that one can utilize nanostructures for the design of solar energy conversion devices. Reproduced from Kamat, P.V., 2007. Meeting the clean energy demand: nanostructure architectures for solar energy conversion. *Journal of Physical Chemistry C* 111, 2834–2860.

emissions can be saved per year (Hussein, 2015). There are three major ways that one can utilize nanostructures for the design of solar energy conversion devices as shown in Fig. 4 (Kamat, 2007).

Solar cells types

There are various types of solar cells which can be described briefly as follows (Hussein, 2015):

- Dye-sensitized solar cell (DSSC):

This type of solar cells enables optical absorption and charge separation/injection by associating a dye sensitizer (a light-absorbing material) with a wide-bandgap semiconductor of nano-crystalline morphology as the photoanode. It is based on the combination of interpenetrating networks of mesoscopic semiconductor materials with electrolytes as alternatives to the p–n junctions of inorganic solid-state semiconductors in conventional solar cells.

Generally, a regular DSSC device consists of a working electrode, dye molecules, electrolytes, a spacer, and a counter electrode as shown in Fig. 5, (Hussein, 2015). The working electrode contains the as-prepared hierarchically porous structured materials, where a great number of dyes can be loaded inside the hierarchically porous structures (Sun *et al.*, 2016). On the other hand, the porous structures are beneficial for light harvesting via multiple light scattering and reflections. It is well known that the macrochannels in hierarchically porous materials play a role as light harvesters, allowing the deep penetration of light in materials due to the scattering effect of the longer pathway length in macrochannels.

The utilization of nanoporous materials improves light absorption, resulting in high power conversion efficiency. So far, the most widely studied hierarchically porous nanostructures are TiO_2 , ZnO and the composites based on them due to their easily controlled porous structures (Mor *et al.*, 2006; Liu *et al.*, 1998; Keis *et al.*, 2002; Tennakone *et al.*, 1995; Chappel and Zaban, 2002; Gebeyehu *et al.*, 2001; Reijnen *et al.*, 2002; Sun *et al.*, 2016), despite many other materials also being used for DSSCs (Sun *et al.*, 2016).

- Organic-polymer-based PV solar cell (OPV):

In this type, excitons are separated in to free electron–hole pairs by the effective field created across the heterojunction between two dissimilar organic materials, known as the donor and acceptor molecules. This type is produced as a result of the increasing requirements for expensive renewable energy sources, as one option for the production of energy from light at very low-cost.

Solar cells based on thin polymer films are particularly attractive because of their ease of processing, mechanical flexibility, and potential for low cost fabrication of large areas. Additionally, their material properties can be tailored by modifying their chemical makeup, resulting in greater customization than traditional solar cells allow. Although significant progress has been made, the efficiency of converting solar energy into electrical power obtained with plastic solar cells still does not warrant commercialization: the most efficient devices have an efficiency of 4%–5% (Askari Mohammad Bagher, 2014). Many crucial studies have been achieved to understand what limits their performance to improve the efficiency of plastic solar cells (Askari Mohammad Bagher, 2014; Antonio Facchetti, 2013; Chiechi *et al.*, 2013; Mayer *et al.*, 2007; Kumar *et al.* 2018; Wang *et al.*, 2018; Chen *et al.*, 2018).

Fig. 5 Schematic principle of a dye-sensitized solar cell. Reproduced from Hussein, A.K., 2015. Applications of nanotechnology in renewable energies – A comprehensive overview and understanding. *Renewable and Sustainable Energy Reviews* 42, 460–476. doi: 10.1016/j.rser.2014.10.027.

- Hot carrier solar cells:

The term hot carrier solar cell (HCSC) was coined by Ross and Nozik to overcome the Shockley-Queisser efficiency limit in simple photovoltaic devices (Farrell *et al.*, 2011). In this type, a free electron is bumped high into the conduction band by a too energetic photon. Therefore, its electronic temperature becomes quite hot (as high as 3000 K). The hot electron will relax to the bottom of the conduction band, typically within a few hundred femtoseconds, imparting heat to the lattice as it does so. This type of solar cells has the following advantages, (Hussein, 2015):

- (1) Using a high-energy electron will increase the photovoltage of the device as well as its efficiency.
- (2) The excess energy will be prevented by heating the device and by lowering its efficiency.

There have been several studies to improve the efficiency of hot carrier solar cells by investigating the following: design and fabrication of HCSC, using different materials, modeling and predictions different parameters (Takeda *et al.*, 2009; Farrell *et al.*, 2011; Yang *et al.*, 2018).

Fuel Cell

A fuel cell is an electrochemical energy conversion device which converts the chemical hydrogen and oxygen into water, and in the process it produces electricity. Most fuel cells today use hydrogen and oxygen as the chemicals (Dzhafarov and Yuksel, 2011).

The fuel can be of fossil origin or come from renewable energy. With fossil origin the primarily of gases produced from natural gas, oil, or coal. They comprise hydrogen, CO, methane or propane, methanol, gasoline or diesel, or mixtures such as syngas or coal gas (both mainly $H_2 + CO$). Fuels from renewables comprise primarily hydrogen, but also some what we may call hydrogen carriers; methanol, ammonia, etc. Recently, the focus has been put on biofuels (alcohols, bio-diesel, etc.) from the organic harvest of sunlight. Fuel cells offer potential advantages in efficiency and environment-friendly operation for all types of fuels (Truls, 2013).

The fuel cell provides a DC (direct current) voltage that can be used to power motors, lights or number of electrical appliances.

Fuel cells are made up of three segments: the anode, the electrolyte, and the cathode, where the catalyst on the anode can oxidize the fuel into a positively charged ion and a negatively charged electron and the catalyst on the cathode turn the ions into

Table 3 Types of fuel cells

<i>Fuel cell types</i>	<i>Fuel</i>	<i>Efficiency (%)</i>	<i>Operating temp. (°C)</i>
PEM	H ₂	40–50	80
Direct Methanol (DMFC)	Methanol	35	80
	Ethanol		
Solid Oxide (SOFC)	H ₂ , CO, CH ₄	45–55	700
Molten Carbonate (MCFC)	H ₂ , CO, CH ₄	50–60	650
Phosphoric Acid (PAFC)	H ₂	40–50	190
Alkaline (AFC)	H ₂	50	50

waste chemicals. Therefore, the catalysts on both electrodes are very important for a fuel cell (Sun *et al.*, 2016). From the viewpoint of the catalysts used in fuel cells, the high surface areas, large pore volumes and, in particular, interconnected macro-nano porosity of the supports on both electrodes are essential owing to the fact that higher surface areas, larger pore volumes and interconnected macro-nano porosity can allow a better dispersion for the active catalysts and offer an open network around the active catalysts for facile diffusion of fuels and products. So far, porous carbon-supported Pt and Pt-based catalysts have been generally considered to be the most common electrocatalysts for fuel cells (Sun *et al.*, 2016). However, the high cost, quick CO poisoning and slow kinetics of fuel oxidation severely restrict their commercial applications. Pursuing low-cost electrocatalysts with highly improved kinetics is urgent. Great efforts have been made to search for efficient, durable and inexpensive alternatives to Pt-based catalysts, such as Pd-based catalysts and metal-free catalysts.

Types of fuel cells

The existing fuel cells are usually classified by their operating type and the type of electrolyte they use. The main types of fuel cells are given in Table 3, (Dzhafarov and Yuksel, 2011). In this article, the PEM fuel cells type will be focused, for it's a widespread, and its uses and multiple applications.

- Polymer exchange membrane fuel cell (PEM or PEMFC).

The PEM is the most likely candidate for portable and transportation applications. The PEM has a high power density and a relatively low operation temperature (ranging from 80 to 120°C). PEM type fuel cell consists of two electrodes (the anode and cathode) and the electrolyte between them. The electrodes of the fuel cell are thin layers of material, with the platinum catalyst dispersed in carbon, which is applied to each side of the membrane, yielding what is known as a Membrane Electrode Assembly (MEA) as shown in Fig. 6, (Dzhafarov and Yuksel, 2011). The anode, the negative post of the fuel, has several jobs. It conducts the electrons that are freed from the hydrogen molecules so that they can be used in an external circuit. It has channels etched into it that disperse the hydrogen gas equally over the surface of the catalyst. The cathode, the positive post of the fuel cell, has channels etched into it that distribute the oxygen to the surface of the catalyst. It also conducts the electrons back from the external circuit to the catalyst, where they can recombine with the hydrogen ions and oxygen to form water. The electrolyte is the proton exchange membrane. PEM can be made from either pure polymer membranes or from composite membranes where other materials are embedded in a polymer matrix. One of the most common and commercially available PEM material is Nafion, a DuPont product.

The membrane presents a solid polymer having negative ionic sites attached to polymer chains. When such a membrane is hydrated (having water absorbed into it), hydrogen ions (protons) can move among the sites so that the protons can be transported across the membrane. The membrane only conducts positively charged ions and blocks electrons. For a PEMFC, the membrane must be hydrated to function and remain stable. The catalyst (electrode) is a special material that facilitates the reaction of oxygen and hydrogen. It is usually made of platinum nano-particles very thinly coated onto carbon paper or cloth. The catalyst is rough and porous so that the maximum surface area of the platinum can be exposed to the hydrogen or oxygen. When an H₂ molecule comes in contact with the platinum catalyst on the anode side, it splits H₂ into two H⁺ ions (protons) and two electrons (e⁻). The electrons are conducted through the anode, where they make their way through the external circuit (doing useful work such as turning a motor) and return to the cathode side of the fuel cell. On the cathode side of the fuel cell, oxygen gas (O₂) is being forced through the catalyst, where it forms two oxygen atoms. Each of these atoms has a strong negative charge. This negative charge attracts the two H⁺ ions through the membrane, where they combine with an oxygen atom and two of the electrons from an external circuit to form a water molecule (H₂O), (Dzhafarov and Yuksel, 2011).

Problems of performance, reliability, durability, a restricted allowable ambient-temperature range for operation and cost of miniature PEM fuel cells, for portable devices were related with:

- Materials of polymer membrane and the platinum catalyst,
- Poisoning the platinum catalyst by carbon dioxide during fuel cell operation,
- The large resistance drop in the membrane-electrode-assembly,

Fig. 6 Proton Exchange Membrane (PEM-type hydrogen fuel cell). Reproduced from Dzhaifarov, T., Yuksel, S.A., 2011. Nano-porous silicon-based mini hydrogen fuel cells, Chapter 13. In: Manzanera, M. (Ed.), *Alternative Fuel*. InTech, p. 311. (ISBN: 978-953-307-372-9).

- Compatibility of DMFC technology fabrication with standard microtechnology.

Many research works have attempted to solve these problems, especially about nonporous materials and their structures (Sun *et al.*, 2016; Dzhaifarov and Yuksel, 2011; Truls, 2013; Candelaria *et al.*, 2012; Wallace *et al.*, 2009; Wolfgang Luther, 2008).

Summary and Remarks

Energy generated via renewable energy strategies is critical to various aspects of global human development, including harmony, equity, employment, ecosystems, and environmental protection. Alternative energy sources should be derived from geothermal, hydrothermal, solar, wind, nuclear and other renewable resources. Several strategies have been attempted to produce a clean energy using green technologies. One of these techniques is using energy conversion forms. This article aims to introduce the Nano-porous materials applications in an energy conversion, particularly in solar cells energy and fuel cells. In spite of the increased efficiency of the conversion of energy using nano-porous particles, by using the green technologies, they still need more research works using new materials with different structures, achieving higher reliability of the system used and more cost reduction and less polluting environment.

Introduction

Nano-structured porous silicon (PSi) has become very attractive for solar cell applications as it can be used for anti-reflection coating to absorb more sunlight, omni-directional Bragg reflector to trap the photons by improving internal reflection, and excellent reusable substrate to reduce the cost of wafer. Besides, through deformation, the porosity of porous Si (PSi) allows Ge, GaN and GaAs to grow in an epitaxial way which was nearly impractical for bulk Si and may bring a paradigm shift in next generation thin film photovoltaic research. On the other hand, Dye Sensitized Solar Cell may surpass all other photovoltaic trends not only for its fascinating state-of-the-art fabrication process but also for the prospect of overall cell efficiency, even though the efficiency of DSSC ($\eta \approx 11\%$) is still far behind of PSi ($\eta \approx 18\%$). These porous ceramic solar cells are beneficial especially for low light environment.

Fuel cells are considered as the most efficient and sustainable tool to combat energy crisis and environment pollution because of their higher efficiency in converting chemical energy into electrical energy directly by a combustion and pollution free operation. Fuel cells generate electricity and heat by electrochemical process of redox reaction between fuel (hydrocarbons, H_2) and oxidant (O_2) through porous electrodes, mostly ceramic, and ion conducting non-porous electrolyte. In this paper, the variety of porous ceramic materials for fuel cell application is reviewed briefly.

Porous Ceramics as Solar Cells

Porous Silicon Solar Cell

In 1956, Uhlir and Uhlir first noticed that electrochemical etching creates round shaped pores instead of polishing the Si and Ge wafers which was then quite unusual (Uhlir and Uhlir, 2005). Porous Si wafers have direct and wide bandgap. Si has indirect type 1.12 eV bandgap which means any electromagnetic (EM) spectrum having energy equal or higher than 1.12 eV, it will be absorbed by the material as well as Silicon in this case. This implies that the absorbed EM spectrum definitely have wavelength equal or less than 1107 nm. Consequently the EM spectrum having energy less than 1.12 eV or wavelength higher than 1107 nm will be reflected by the material.

Therefore, Si should be capable of utilizing almost 60%–70% solar spectra but it fails because it enables the Si solar cell to absorb photons having a wide range of energies associated with the spectra. The photoexcitation creates chaotic electron – hole recombination inside of the depletion zone which is undesirable. It is expected that those electrons, generated by photoexcitation, recombine with holes through some specified paths and the travel of electrons through the paths can be utilized. But this expectation hampers when electrons are excited with photons having higher energy than the required bandgap and as a consequence these excess energy turns into heat followed by decreasing the conductivity and ultimately efficiency of the solar cell. In order to increase the efficiency, we need to narrow the solar spectra transmission since we cannot make the solar spectra monochromatic which means we have to increase the bandgap of Si solar cell.

Porous silicon (PSi) as antireflection coating (ARC)

One of the most important factors which limit the efficiency of solar cell is the reflectance of light from its front surface. Due to the refractive index between air and solar cell material, transmission efficiency is highest when incident angle is lowest and with increase in the incident angle, transmission efficiency decreases. From the concept of refractive index which is basically a measure of how much light has been reflected at incident surface, it can be said that to minimize the reflection, the refractive index needs to be decreased. In this way, more light of specific solar spectra (narrowed by increased bandgap) can be transmitted into the solar cell material which in turn increases the net efficiency.

When a thin layer of antireflection coating is placed on the Si solar cell, light is reflected twice – one from the front surface and another from the bottom of the layer. If these two reflected light waves have equal amplitude but out of phase (180°), then they will cancel out each other by resulting a destructive interference (see Fig. 1(a)). For the amplitudes of two light waves to be equal, the refractive index of the coating layer has to be equal to the square root of the refractive index of the substrate. Single and multilayer porous silicon structure used as an antireflective coating (ARC) are illustrated in Fig. 1.

Although texturizing the front surface has been widely investigated in order to achieve the efficient light trapping, this technique alone could not minimize the reflection below 10% in the wavelength range 400–1000 nm and the reproducibility of state of the art synthesis is another major limiting factor (Dzhafarov *et al.*, 2012; Weiying *et al.*, 2011; Marrero *et al.*, 2009). Hence,

Fig. 1 (a) Schematic diagram of a single layer antireflection coating operation; (b) Schematic diagram of porous Si/textured Si integrated with crystalline Si solar cell; (c) FESEM image of textured Si wafer; (d) FESEM image of one pyramid with porous Si showing uniformity; (e) Schematic multilayer porous Si as ARC, increasing level of darkness and the width of the each film both represent an increasing refractive index (decreasing porosity); $n_{\text{air}} < n_1 < n_2 < n_3 < \dots < n_N < n_{\text{Si}}$. Reproduced from (b) Ho, W.J., *et al.*, 2018. Photovoltaic performance of textured silicon solar cells with MAPbBr₃ perovskite nanophosphors to induce luminescent down-shifting, *Applied Surface Science* 436, pp. 927–933. doi: [10.1016/j.apsusc.2017.12.134](https://doi.org/10.1016/j.apsusc.2017.12.134). (c)–(e) Lv, H., *et al.*, 2012. Porous-pyramids structured silicon surface with low reflectance over a broad band by electrochemical etching, *Applied Surface Science* 258 (14), pp. 5451–5454. doi: [10.1016/j.apsusc.2012.02.033](https://doi.org/10.1016/j.apsusc.2012.02.033).

integration of an antireflection coating has become useful for Silicon solar cell as it reduces the reflectance up to 0.1% and maximizes the efficiency up to 15%–18% (Green *et al.*, 2015; Gao *et al.*, 2018; Kim and Lim, 2015; Silva *et al.*, 2014).

In antireflection coating, the encapsulated and/or front thin layers have refractive index between 1 (air) to 3.84 (bulk Si) which are usually fabricated using plasma enhanced chemical vapor deposition (PECVD) technique. Among them widely investigated Single Layer Antireflection Coatings include SiN_x, Ta₂O₃, ZnS, CeO₂, Al₂O₃ and Double Layer Antireflection Coatings include SiO₂/TiO₂ and ZnS/MgF₂. But it is worth mentioning here that due to state of the art synthesis technique, these ARCs are not cost effective for large scale industrial applications.

While two important pathways – texturizing and vacuum deposited ARCs fade away, integration of porous Silicon as ARC has appeared as a silver lining to reduce the reflection from front surface. Because, the fundamental requirements of antireflection for Single Layer ARC can only be satisfied by one wavelength as well as the light waves reflected from one incident angle and this does not improve much with multilayers introduction on the crystalline Si solar cell. On the other side, refractive index can be easily controlled by varying the porosity in porous silicon (PSi) ARC. Prasad *et al.* (1982) first demonstrated that porous Si as ARC reduces the optical loss from 37% to 8% of silicon solar cell and since then different approaches have been reported by many researchers all around the world. Table 1 lists such kind of studies which have been reported after 2004.

Porous silicon (PSi) as omnidirectional bragg reflector

Like the optical loss, carrier recombination is equally detrimental for solar energy to current conversion in solar devices. Hence, substitution of metal back reflectors, which are highly absorbing and poor reflector, with dielectric materials offered superior advantages by increasing internal reflection to generate more carriers in active cell. However, due to state of the art deposition techniques, the concept of dielectric materials as omnidirectional Bragg reflector recently has been replaced with a concept of using porous Si for its refractive index tuning compatibility and easier fabrication techniques.

Bhandaru *et al.* (2016) demonstrated that using porous amorphous Si back reflector for amorphous Si solar cell, both short circuit current density and overall cell efficiency were improved by 30% compared to flat metal back reflector amorphous Si solar cell device (For metal back reflector: $\eta = 2.7\%$, $J_{sc} = 6.5 \text{ mA/cm}^2$, $V_{oc} = 732 \text{ mV}$, $FF = 0.57$ and porous amorphous Si reflector: $\eta = 3.5\%$, $J_{sc} = 8.66 \text{ mA/cm}^2$, $V_{oc} = 742 \text{ mV}$, $FF = 0.56$).

Ghannam *et al.* (2010) reported a five layered porous Si back reflectors on back of a textured crystalline Si cell where the bottom two layers had 22.5% porosity (each layer thickness was 157 nm) and the rest three layers had 55% porosity (each layer thickness

Table 1 Porous silicon surface improved antireflection properties with different approaches

Approaches	Reflectance (%)	Wavelength (nm)	Ref.
PSi/textured – Si	4.2	400–900	(Xiao <i>et al.</i> , 2010)
PSi/textured – Si	11.34	400–1000	(Chaoui <i>et al.</i> , 2013)
PSi/ (n ⁺ – p) Si	4	400–1000	(Dzhafarov <i>et al.</i> , 2012)
PSi/ textured – Si	3.67–6.15	400–1040	(Weiyang <i>et al.</i> , 2011)
PSi/ textured – Si	< 4	400–800	(Marrero <i>et al.</i> , 2009)
PSi/ textured – Si	7.5	400–1100	(Druzhinin <i>et al.</i> , 2016)
Multilayer PSi/textured – Si	1.9	200–2000	(Lv <i>et al.</i> , 2012)
Multilayer PSi/Si (in air)	3	400–1100	(Selj <i>et al.</i> , 2011)
Multilayer PSi/Si (under glass)	1.4	400–1100	(Selj <i>et al.</i> , 2011)
Multilayer PSi/textured – Si	< 5	400–1000	(Kwon <i>et al.</i> , 2011)
Double Layer ZnO/PSi/Si	< 5	450–850	(Salman <i>et al.</i> , 2012)
Double Layer SiO _x N _y /PSi/ polycrystalline Si	< 5	500–1000	(Marrero <i>et al.</i> , 2009)
Double Layer SiO ₂ /PSi/Si	3.8	400–1000	(Remache <i>et al.</i> , 2010)
Double Layer SiO _x N _y /PSi/ polycrystalline Si	6	450–1100	(Rabha <i>et al.</i> , 2011)
Double Layer Al ₂ O ₃ /PSi/ monocrystalline Si	7	400–1000	(Rabha <i>et al.</i> , 2013)
Double Layer SiO _x N _y /PSi/Si	0.01	430–670	(Search <i>et al.</i> , 2006)
Double Layer SiO _x N _y /PSi/Si	< 7	400–900	(Search <i>et al.</i> , 2006)
Double Layer DLC/PSi/Si	< 2.5	400–850	(Aroutiounian <i>et al.</i> , 2004)
Double Layer DLC/PSi/Si	≈ 1	400 and 700 nm only	(Aroutiounian <i>et al.</i> , 2004)

was 256 nm). The overall cell efficiency (η), short circuit current density (J_{sc}), open circuit voltage (V_{oc}) and fill factor (FF) were found as 12%, 26.99 mA/cm², 609.2 mV and 0.73 respectively.

Kuzma-Filipek *et al.* (2008) showed that low (23%)/high (42%)/low (23%)/.../high (42%) porosity Si layers as back reflector on crystalline Si exhibits internal reflection R_B of 95% in 900–1050 nm wavelength region for 20 bilayers and in 800–1100 nm wavelength region for 60 bilayers. The overall cell efficiency (η), short circuit current density (J_{sc}), open circuit voltage (V_{oc}) and fill factor (FF) for 40 bilayers and 60 chirped bilayers were found as 13.3%, 28.7 mA/cm², 598 mV, 0.78 and 13.9%, 29.6 mA/cm², 605 mV, 0.78 respectively.

Bougoffa *et al.* (2017) investigated the improvement of internal reflection by stacking multiple layers of porous Si as back reflectors on textured crystalline Si solar cell. They showed that for single double-porosity Si layer, internal reflection R_B increases from 18% to 40% due to porosity variation. Again, for three double-porosity Si layers, the porosity variation improved internal reflection R_B from 51% to 80% as depicted in Fig. 2.

Multiple bilayer porous Si back reflectors, improved the internal reflection, have been reported in several literatures i.e., R_B = 62% for multicrystalline Si and more than 90% for single crystalline Si (Ivanov *et al.*, 2013), R_B = almost 100% except for a small dip for p polarized light which can be minimized by chirped like approach and bilayer comprised 70% and 20% porosity Si (Jiang *et al.*, 2014), R_B = 80% for 15 bilayer low and high porosity Si (Kuzma-Filipek *et al.*, 2007), R_B = 86% for single layer Si/PSi comprising 60% porosity and R_B = 83% for Si/PSi/SiN_x (Remache *et al.*, 2016).

Porous silicon (PSi) as a promising substrate for thin film solar cell

Layer transfer process using porous silicon as reusable substrate has raised enormous enthusiasm among researchers since last decade for its promising cost effectiveness and facile state of the art fabrication techniques. In a typical layer transfer process to make thin crystalline Si solar cell as depicted in Fig. 3, a monocrystalline silicon wafer is first electrochemically etched which turns it into a porous Si wafer comprised of two different porosity layers – low (20%–30%) and high (above 50%). Appropriate annealing allows the low porosity layer to act as an excellent monocrystalline ground for growing epitaxial Si on it. Once the epitaxial layer is deposited, the epitaxial layer with low porosity Si layer can be detached through the high porosity layer and thus the remaining high porosity Si wafer becomes further reusable. However, the process sequence i.e., detachment of epitaxial Si layer from high porosity Si substrate, gluing that on a foreign substrate and device fabrication on epitaxial Si layer may vary depending on the research requirements (Solanki *et al.*, 2004).

Brendel *et al.* (2003) achieved 15.4% cell efficiency for 25 μ m thick crystalline Si solar cell where short circuit current density (J_{sc}), open circuit voltage (V_{oc}) and fill factor (FF) were found as 32.7 mA/cm², 623 mV and 0.755, respectively. Later, Reuter *et al.* (2009) fabricated 50 μ m thick crystalline Si solar cell of 17% cell efficiency where short circuit current density (J_{sc}), open circuit voltage (V_{oc}) and fill factor (FF) were found as 36 mA/cm², 634 mV and 0.746 respectively. Petermann *et al.* (2012) improved the cell efficiency to 19.1% for a 43 μ m thick crystalline Si solar cell where short circuit current density (J_{sc}), open circuit voltage (V_{oc}) and fill factor (FF) were found as 37.8 mA/cm², 650 mV and 0.776, respectively. Wang *et al.* (2014) used steel as foreign substrate and achieved 16.8% cell efficiency for 18 μ m thin Si solar cell with short circuit current density (J_{sc}), open circuit voltage (V_{oc}) and fill factor (FF) were found as 34.5 mA/cm², 632 mV and 0.77, respectively.

Fig. 2 Multiple stacking of porous Si layers enhanced internal reflection. Reproduced from Bougoffa, A., *et al.*, 2017. Analytical model of front texturization effect on silicon solar cell with porous silicon at the backside, *Optical and Quantum Electronics* 49 (1), pp. 1–13. doi: [10.1007/s11082-016-0864-8](https://doi.org/10.1007/s11082-016-0864-8).

Fig. 3 Steps of porous layer transfer processes using porous silicon as a sacrificial layer for obtaining thin monocrystalline silicon films on cost-effective substrates: (a) a double porosity structure (high-porosity layer beneath low-porosity layer) formation on starting silicon substrate by anodization; (b) thermal annealing of porous silicon and active layer deposition: annealed low-porosity layer acts as a good seeding layer for epitaxial layer deposition and voids with weak silicon pillars form in high-porosity layer acts as a separation layer; (c) Device fabrication; (d) Separation of epitaxial layer from the starting silicon substrate and transfer onto foreign substrate by gluing it with an adhesive layer and applying mechanical force; (e) SEM image showing epitaxial layer/low porosity/high porosity/Si wafer. Reproduced from (a)–(d) Solanki, C.S., *et al.*, 2004. Porous silicon layer transfer processes for solar cells, *Solar Energy Materials and Solar Cells* 83 (1), pp. 101–113. doi: [10.1016/j.solmat.2004.02.016](https://doi.org/10.1016/j.solmat.2004.02.016). (e) Radhakrishnan, H., *et al.*, 2015. Kerfless layer-transfer of thin epitaxial silicon foils using novel multiple layer porous silicon stacks with near 100% detachment yield and large minority carrier diffusion lengths, *Solar Energy Materials and Solar Cells* 135, pp. 113–123. doi: [10.1016/j.solmat.2014.10.049](https://doi.org/10.1016/j.solmat.2014.10.049).

Apart from thin film Si solar cell, porous Si has appeared as a remarkable buffer layer for Ge (Calabrese *et al.*, 2014; Aouassa *et al.*, 2012; Mahamdi *et al.*, 2018; Gouder *et al.*, 2014), GaN (Abud *et al.*, 2016; Wu *et al.*, 2018) and GaAs (Wilkins *et al.*, 2013) epitaxial growth. The compatibility of porosity variation allows PSi to deform during epitaxial growth which is not possible for bulk Si due to its large lattice mismatch with those materials and thus porous Si resembles as a promising substrate for multi-junction solar cell devices.

Dye Sensitized Solar Cell

A dye sensitized solar cell is comprised of four different components: photoanode, dye sensitizer, electrolyte and electrode. Usually porous TiO_2 is used as photoanode which is covered by a thin layer of dye sensitizer materials. When sunlight strikes the surface of the thin layer, dye sensitizers get excited and they pass the photon excited electrons to the TiO_2 film which later travelled through

Fig. 4 (a) Schematic working principle of Dye Sensitized Solar Cell (DSSC); LUMO means Lowest Unoccupied Molecular Orbitals and HOMO means Highest Occupied Molecular Orbitals; (b) A cross-sectional photograph of TiO₂ thin film with a film thickness of 1.5 μm. Reproduced from (a) Sengupta, D., *et al.*, 2016. Effects of doping, morphology and film-thickness of photo-anode materials for dye sensitized solar cell application – A review, *Renewable and Sustainable Energy Reviews* 60, pp. 356–376. doi: [10.1016/j.rser.2016.01.104](https://doi.org/10.1016/j.rser.2016.01.104). (b) Kao, M.C., *et al.*, 2009. The effects of the thickness of TiO₂ films on the performance of dye-sensitized solar cells, *Thin Solid Films* 517 (17), pp. 5096–5099. doi: [10.1016/j.tsf.2009.03.102](https://doi.org/10.1016/j.tsf.2009.03.102).

the electrolyte. The redox coupled electrolyte (typically I_3^- and I^-) is attached with a counter electrode to collect the electrons and regenerate the dye. The overall efficiency (η) of DSSC is measured by the following equation:

$$\eta = \frac{V_{oc} J_{sc} FF}{P_{in}} \quad (1)$$

Where, V_{oc} is the open circuit voltage which is actually the measure of the potential difference between TiO₂ and redox potential of electrolyte; J_{sc} is the short circuit current which depends on the light harvesting efficiency of dye sensitizers, electronic conductivity performance of electrolyte and charge collection efficiency of counter electrode; FF (fill factor) represents the ratio of maximum generated power to the product of open circuit voltage and P_{in} is the power of incident light (standard irradiation condition: 100 mW/cm², AM1.5). Working principle of Dye Sensitized Solar Cell (DSSC) is depicted in Fig. 4.

A review on photovoltaic parameters of Dye Sensitized Solar Cell (DSSC) using different approach and photoanode is listed in Table 2.

Porous Ceramics as Fuel Cells

Energy crisis and environmental pollution are the most alarming issues of today's world. Burning of fossil fuels to meet energy requirement have not only reduced the finite reserves of but also caused greenhouse effect by releasing harmful gases. The quest for efficient utilization of renewable energy (like solar, wind energy etc.) and development of sustainable, green energy sources have gathered enormous interest among the researchers. Fuel cells provide a key solution to conversion and storage of energy. In 1838 William Grove invented the first fuel cell by reversing electrolysis of water and named it "wet cell battery" or "Grove cell" (Grove, 1839). Various fuel cells have been developed since then based on electrode and electrolyte types that are listed in Table 3.

Among the varieties of fuel cells, Solid Oxide Fuel Cells (SOFC) and Polymer Electrolyte Membrane (PEM), also known as proton-exchange membrane fuel cell, are most commonly used. In PEM fuel cells, electrolyte material is polymer based, generally PTFE/Teflon and solid (Ni, Ti, stainless steel mesh, porous Carbon) materials are used as electrodes and Pt coated as catalyst on the anode. Each type of fuel cells has its own advantages and limitations. As it can be seen from Table 3 that most of the fuel cells use hydrogen as their fuel which is more costly to produce than other source of energy and it is almost energy neutral (required production energy roughly equal to as it delivers at the end destination). Therefore, the applications of fuel cells are so far very limited. Solid Oxide Fuel Cells (SOFC) has received renewed attention because of hydrogen extraction process. A high operating temperature here allows hydrogen to be extracted directly from natural gas through a catalytic reforming process. Due to the renewed research interest and future prospect, we limit our discussion to SOFC in this paper.

Solid Oxide Fuel Cell

Gauguin first discovered solid electrolyte in 1853 and in 1899 Nernst showed that the conductivity of Y₂O₃ doped ZrO₂ (15 YSZ) rises with increasing temperature (Gauguin, 1853; Nernst, 1899). Baur and Preis finally developed SOFC in 1937

Table 2 Photovoltaic parameters of DSSC using different approach and photoanode

Photoanode	η (%)	V_{oc} (mV)	J_{sc} (mW/cm ²)	FF (%)	Ref.
TiO ₂ nanosphere	8.5	730	17.88	65	(Ye <i>et al.</i> , 2013a)
TiO ₂ microsphere	7.94	690	15.42	66	(Wang <i>et al.</i> , 2013a)
TiO ₂ nanosphere	11.18	846	17.73	75	(Humphry-Baker <i>et al.</i> , 2013)
TiO ₂ nanorod	4.4	739	8.88	67	(Hafez <i>et al.</i> , 2010)
TiO ₂ nanorod	7.91	700	20.49	54.5	(Lv <i>et al.</i> , 2013)
TiO ₂ nanofiber	4.01	770	8.67	60	(Song <i>et al.</i> , 2004)
TiO ₂ nanosphere	8.44	804	14.57	51.9	(Ye <i>et al.</i> , 2013b)
TiO ₂ nanofiber	10.30	640	22.4	72	(Chuangchote <i>et al.</i> , 2008)
